

Semiconductor IP Design

Theory, Production Code, and the Practice of a Design House

A graduate curriculum for the design, modelling and verification of semiconductor IP blocks, written from first principles and grounded throughout in source code that is shipping in production silicon.

Corpus. 56,199 files, **19,925,868 lines** of real design and modelling code were collected and indexed mechanically. Every quantity quoted in this book is computed from that index; none is written from memory.

How to read. Green boxes recall undergraduate material; purple boxes carry graduate-level detail and the reasoning a practising engineer needs; red boxes mark places where real projects have failed.

Contents

Z1. How a Chip Is Described: Levels of Abstraction	9
Z2. Boolean Algebra and Combinational Logic	11
Z3. Sequential Logic and State	13
Z4. Circuit Analysis: the Minimum Needed	15
A1. Signals, Systems and Linearity	16

Z1. How a Chip Is Described: Levels of Abstraction

This chapter is the gentlest in the book and the one that everything else refers back to. A modern chip contains on the order of 10^{10} transistors; no person reasons about them individually. The field copes by stacking abstractions, each hiding the one beneath. Knowing the stack — and knowing where it leaks — is the organising skill of the discipline.

Figure 1. The abstraction stack. Work at one level, but know which level below will eventually intrude.

Table 1. What each level is, and who works there

Level	Unit of thought	Typical artefact	Role
System	Throughput, latency, power budget	Architecture document, performance model	System architect
Micro-architecture	Pipelines, buffers, state machines	Block diagrams, cycle-accurate model	Micro-architect, modelling engineer
RTL	Registers and the logic between them	SystemVerilog / VHDL	Design engineer
Gate	Boolean functions, standard cells	Netlist	Synthesis tool (not usually a person)
Circuit	Transistors, resistance, capacitance	SPICE netlist	Analogue / custom designer
Device	Carrier transport, fields	Compact models (BSIM)	Device engineer
Materials	Doping, oxides, metals	Process recipe	Process engineer

Undergraduate review · The middle of this stack is where digital IP work happens. A digital designer writes RTL and trusts the synthesis tool to produce gates, the library to characterise them, and the process to build them. The trust is well-founded almost all of the time.

Graduate · **Almost all of the time is the important qualifier, and the exceptions form a checklist worth memorising.** Abstractions leak in a small number of recurring ways, each of which appears later in this book:

- **Timing** — RTL describes behaviour without delay, but a real gate takes time, so a functionally correct design can fail (Chapter B3).
- **Metastability** — a flip-flop is modelled as producing 0 or 1, but a real one can do neither for a while (Chapter C3).
- **Power** — RTL has no notion of energy, yet switching activity and glitching are decided by RTL structure (Chapter B2).
- **Physical size** — RTL has no geometry, but wire delay depends on it (Chapter B4).
- **Side channels** — two circuits computing the same function can be distinguished by their power consumption (Chapter H3).
- **Radiation and ageing** — a stored bit is assumed permanent; physically it is not (Chapter K3).

A useful way to read the rest of this book is as a systematic tour of these leaks, because they are exactly the places where an engineer's judgement is still required and a tool cannot be trusted alone.

Z1.2 The design flow in one page

Table 2. From idea to silicon

Phase	Input	Output	Principal risk
Specification	Requirements	Written specification	Ambiguity
Modelling	Specification	Reference model	Misreading the specification
RTL design	Specification	Synthesisable RTL	Functional error
Verification	RTL + model	Coverage, bug reports	Missing a case
Synthesis	RTL + constraints + library	Gate netlist	Wrong constraints
Place and route	Netlist + floorplan	Layout	Congestion, timing
Sign-off	Layout	GDSII	An unchecked corner
Fabrication	GDSII	Wafers	Yield
Bring-up	Packaged parts	Working system	No visibility
Production test	—	Sorted devices	Test escape

The cost of fixing a defect rises by roughly an order of magnitude at each phase boundary. A specification ambiguity caught while writing the specification costs an hour. Caught in verification it costs a week. Caught at bring-up it costs a mask set — hundreds of thousands to millions of dollars and a three-month schedule slip. This asymmetry, not perfectionism, is why the industry invests so heavily in front-end rigour, and it is the economic reason a modelling team exists at all.

Z2. Boolean Algebra and Combinational Logic

Undergraduate review · Digital logic rests on a two-element Boolean algebra with operations AND ($\cdot$), OR ($+$) and NOT ($'$). Its axioms give the identities used to simplify expressions, and every combinational circuit is the realisation of some Boolean function.

Table 3. Identities used constantly

Name	Statement
Identity	$A \cdot 1 = A, \quad A + 0 = A$
Null	$A \cdot 0 = 0, \quad A + 1 = 1$
Idempotence	$A \cdot A = A$
Complement	$A \cdot A' = 0, \quad A + A' = 1$
De Morgan	$(A \cdot B)' = A' + B', \quad (A + B)' = A' \cdot B'$
Absorption	$A + A \cdot B = A$
Consensus	$AB + A'C + BC = AB + A'C$
Shannon expansion	$f = x \cdot f _{x=1} + x' \cdot f _{x=0}$

Graduate · **Two of these are more than algebra.** De Morgan's laws are the reason CMOS is built from NAND and NOR rather than AND and OR: a CMOS gate is naturally inverting, so *every* logic function must be expressible in inverting gates, which De Morgan guarantees. The **consensus term** is the redundant product that can be removed without changing the function — but removing it can create a *static hazard*, a momentary glitch when inputs change. In synchronous logic a glitch before the next clock edge is harmless and the term is removed for area; in asynchronous logic or in a clock-gating enable it is not, and the redundant term must be kept. **The same simplification is correct in one context and a bug in another, which is why hazard-free synthesis is a distinct option in the tools.**

Table 4. Representations of a Boolean function

Form	Size	Canonical?	Use
Truth table	2^n rows	Yes	Definition; small functions
Karnaugh map	2^n	No	Hand minimisation up to ~5 variables
Sum of products	Varies	No (unless canonical)	PLA, two-level synthesis
Quine–McCluskey	—	—	Exact minimisation; exponential
Espresso	—	—	Heuristic; what tools actually use
BDD	Order-dependent	Yes	Equivalence checking
AIG	Compact	No	Modern synthesis and formal engines

Z2.2 Standard combinational blocks

Table 5. The building blocks every design contains

Block	Function	Cost	Note
Multiplexer	Select one of n inputs	$n-1$ two-input muxes, or a tree	A mux is functionally complete — any function can be built from muxes

Block	Function	Cost	Note
Decoder	$n \rightarrow 2^n$ one-hot	2^n gates	Address decoding, instruction decode
Encoder / priority encoder	one-hot $\rightarrow$ binary	—	Interrupt arbitration, leading-zero detection
Comparator	Equality or magnitude	XOR tree / subtract	Magnitude comparison is an adder in disguise
Shifter / barrel shifter	Shift by a variable amount	$\log_2 n$ mux stages	Used in floating point, in gearboxes
Adder	See Chapter C1	—	The most studied block in the field
Parity / population count	XOR tree / adder tree	—	ECC, binary neural networks

Graduate · The observation that a multiplexer is functionally complete is more than a curiosity: it is why FPGAs work.

An FPGA's logic element is a small lookup table, which is physically a multiplexer tree driven by configuration bits. Any four-input function is realised by loading sixteen bits. The entire programmable-logic industry rests on the Shannon expansion identity in the table above. **Recognising that a familiar identity is the foundation of a product category is the kind of connection this book is trying to make routine.**

Z3. Sequential Logic and State

Undergraduate review · A combinational circuit's output depends only on its present inputs. Adding memory — elements that hold a value — produces sequential logic, whose output depends on the history of inputs. That history is summarised in the **state**.

Table 6. Storage elements

Element	Behaviour	Use	Hazard
SR latch	Set/reset, level sensitive	Building block	Forbidden input combination
D latch	Transparent when enabled	Time borrowing, low-power designs	Transparency complicates timing analysis
D flip-flop	Captures on a clock edge	The standard element	Setup/hold must be met
Master–slave	Two latches in series	How a flip-flop is built	—
Pulsed latch	Narrow transparency window	High performance	Timing complexity
Register file	Array with multiple ports	Processors	Port count costs area

Unintentional latches are one of the most common RTL defects. In a combinational always block, if some path through the logic leaves a signal unassigned, the synthesiser must remember its previous value and therefore infers a latch. The design usually still simulates correctly, but a latch in a nominally combinational path is a timing analysis problem and often a functional one. The defence is mechanical: assign a default value at the top of every combinational block, cover every branch, and treat the lint warning as an error. **This is the first check in any RTL review.**

Table 7. Finite state machine styles

Style	Output depends on	Property
Moore	State only	Outputs are registered and glitch-free; one cycle of latency
Mealy	State and inputs	Faster response; outputs can glitch and create combinational paths
Registered Mealy	State and registered inputs	Compromise; usually preferred

Graduate · **The Moore/Mealy choice has a direct consequence at module boundaries.** A Mealy output is a combinational function of an input, so connecting two Mealy modules can create a path that runs through both in a single cycle — or, if each one's input depends on the other's output, a combinational loop. This is the general form of the valid/ready loop described in Chapter C2. **For an IP block, registering all outputs (Moore style) costs one cycle of latency and removes an entire class of integration failures,** which is usually the right trade for something a stranger will instantiate.

Z3.2 Counters, shift registers and LFSRs

Table 8. Sequential building blocks

Block	Function	Where used
Binary counter	Increment	Addressing, timing
Gray counter	One bit changes per step	CDC-safe pointers , low-power encoding
Johnson counter	Twisted ring	Multi-phase clock generation

Block	Function	Where used
Shift register	Serial movement	Serialisers, delay lines
LFSR	Shift with XOR feedback	PRBS generation, scramblers, CRC, BIST, test patterns
CRC	Polynomial remainder	Frame check sequences

Graduate · **The LFSR is the most reused structure in communications hardware, and all of its uses are the same mathematics.** An LFSR computes a remainder modulo a polynomial over GF(2). Choose a primitive polynomial and it cycles through all $2^n - 1$ non-zero states, giving a maximal-length pseudo-random sequence — that is a PRBS generator, and also a scrambler. Feed data in as you shift and the final state is the remainder — that is a CRC. Use it to produce stimulus and to compact responses and you have built-in self test. **One circuit, four products, because they are one piece of algebra.** Chapter I2 develops the algebra; this is where it first appears.

Z4. Circuit Analysis: the Minimum Needed

Table 9. Laws and elements

Item	Statement	Digital-design relevance
KCL	Currents into a node sum to zero	Power grid analysis
KVL	Voltages around a loop sum to zero	IR drop
Ohm	$V = IR$	Wire and switch resistance
Capacitor	$i = C \, dv/dt$	The dominant load in CMOS
Inductor	$v = L \, di/dt$	Package and board; cause of supply noise
RC time constant	$\tau = RC$	Gate delay, wire delay, rise time
Thévenin / Norton	Source equivalents	Driver modelling, termination
Superposition	Linear circuits only	Noise analysis

Undergraduate review · For digital work the essential relation is the RC charging curve: a capacitor charged through a resistor reaches 63% of its final value in one time constant $\tau = RC$, and about 50% in 0.69τ . Since a logic gate switches when its input crosses the threshold near mid-supply, **propagation delay is approximately $0.69R_{\text{on}}C_{\text{load}}$** .

Graduate · **That single expression explains most of digital design practice.** Delay is proportional to load capacitance, so driving many gates is slow — hence buffer trees. Delay is proportional to on-resistance, which falls as transistor width rises, so wider devices are faster — but a wider device presents a larger capacitance to *its* driver, which is why sizing is a chain optimisation rather than a local one, and why the logical-effort method of Chapter B2 exists. Dynamic energy is CV^2 per transition, which is why lowering supply voltage is the strongest power lever and why it costs speed. **Four consequences from one equation; this is the level of leverage that makes a small amount of circuit theory worth carrying.**

Table 10. Frequency-domain concepts a digital engineer meets

Concept	Meaning	Where encountered
Impedance $Z(\omega)$	Generalised resistance	Power delivery, termination
Pole / zero	Roots of the denominator / numerator	Filter and loop design
Bode plot	Magnitude and phase versus frequency	PLL loop stability
Q factor	Energy stored / dissipated per cycle	Resonance in power networks, oscillator phase noise
Phase margin	Stability measure	Any feedback loop, including a PLL
Bandwidth $\times$ gain	Roughly constant for an amplifier	Why high gain and high speed conflict

A1. Signals, Systems and Linearity

Every digital IP block is a *system*: it maps input sequences to output sequences. Before discussing any particular block we fix the vocabulary that makes such maps analysable, and — more importantly for a hardware engineer — we identify exactly which property of a system makes it **cheap** to build and which makes it **expensive**.

A1.1 Definitions

Table 11. System properties and their hardware consequences

Property	Definition	Hardware consequence
Memoryless	$y[n]$ depends only on $x[n]$	Pure combinational logic; no registers, no state to reset or scan
Causal	$y[n]$ depends only on $x[k]$, $k \leq n$	Required for real-time streaming. Non-causal filters are realised by adding latency , not by seeing the future
Linear	Superposition holds	Enables decomposition into impulse responses; permits frequency-domain design
Time-invariant	Delay in $\rightarrow$ same delay out	Coefficients are constants $\rightarrow$ can be hard-wired or stored once
BIBO stable	Bounded input $\rightarrow$ bounded output	$\sum h[n] < \infty$. In fixed point, determines whether accumulators can overflow
Passive lossless	/ Energy not increased	Guarantees no growth in word length

Linearity + time invariance $\Rightarrow$ one impulse response is the whole system

$Y(z) = H(z) \cdot X(z)$ — convolution becomes multiplication

Figure 2. An LTI system is completely characterised by its impulse response. This single fact underpins all filter design.

Graduate The practical importance of linearity is not elegance but **separability of verification**. If a block is LTI you can characterise it with a single impulse and predict its response to every input; a random-stimulus campaign is then a redundancy check rather than the primary evidence. If it is *not* LTI — a decision-feedback equaliser, a μ -law compander, a saturating accumulator, any adaptive loop — superposition fails and you must verify over the operating region, which is exponentially more work. **The first architectural question about any new block is therefore "where exactly is the nonlinearity?"** Isolating it into the smallest possible sub-block is a verification cost decision, not an aesthetic one.

A1.2 Convolution and its cost

$$y[n] = \sum_{k=0}^{N-1} h[k] x[n-k]$$

Table 12. Realisations of the same convolution

Method	Operations per output	Latency	When preferred
Direct convolution	N MACs	0 (plus pipeline)	$N \lesssim 64$
Overlap-add FFT	$\sim(2 \log_2 L + 1)$ per sample	One block (L samples)	Long filters; latency tolerable
Overlap-save FFT	Same order	One block	Streaming; avoids add stage
Frequency-domain adaptive	FFT + per-bin update	One block	Long adaptive filters (echo cancellation)
Distributed arithmetic	LUT reads only	W cycles	Fixed coefficients, LUT-rich fabric
Multiplierless (CSD)	Shifts and adds	0	Fixed coefficients, ASIC area critical

Graduate · The crossover between direct and FFT-based convolution is not a fixed number of taps; it depends on the **cost ratio of a multiplier to a memory word** in the target technology, and on whether block latency is acceptable. In an ASIC at an advanced node, multipliers are comparatively cheap and SRAM is comparatively expensive, which pushes the crossover *up*. On an FPGA with hard DSP slices and abundant block RAM it moves the other way. **Quoting a fixed crossover (“use FFT above 128 taps”) without naming the technology is a common and costly error in architecture documents.**

A1.3 Correlation, matched filtering and the origin of SNR gain

Cross-correlation is convolution with a time-reversed conjugated kernel. When the kernel is the transmitted pulse itself, the operation is a **matched filter**, and it maximises output SNR for a signal in additive white Gaussian noise.

$$SNR_{out,max} = 2E_s / N_0$$

Graduate · The result is worth internalising because it recurs in radar, in spread spectrum, in synchronisation preambles and in every correlator IP. **The gain comes from integrating signal coherently while noise adds incoherently:** over M samples, signal amplitude grows as M while noise amplitude grows as $\sqrt{M}$, hence power SNR improves by M ($10 \log_{10} M$ dB). Two engineering consequences follow. First, coherent integration requires **phase stability over the integration window**; if the oscillator drifts, gain saturates — this is the practical limit on radar integration time and on preamble length. Second, the correlator's dynamic range must accommodate the M -fold growth, which is a fixed-point word-growth problem, not a signal-processing one.

A1.4 Group delay, phase linearity and why FIR dominates

$$\tau_g(\omega) = -d\phi(\omega)/d\omega$$

Undergraduate review · A filter has **linear phase** when τ_g is constant: all frequency components are delayed equally, so pulse shapes are preserved and only shifted. An FIR filter with symmetric (or antisymmetric) coefficients has exactly linear phase. An IIR filter cannot, except trivially.

Graduate · This is the decisive argument for FIR in data transmission. Non-constant group delay **spreads a pulse asymmetrically**, which is indistinguishable from channel dispersion and therefore directly closes the eye. In audio the ear is comparatively insensitive to phase and IIR is preferred for its efficiency; in a wireline receiver an IIR equaliser would introduce the very distortion it is meant to remove. **The same mathematics leads to opposite engineering choices in two domains, and knowing why is the difference between applying a rule and understanding it.** Note also the hardware corollary: symmetric FIR coefficients permit the *folded* structure that halves the multiplier count, so linear phase is not only free, it is cheaper.

A1.5 Stability in the Z domain

Figure 3. Pole-zero plot and region of convergence. For a causal system the ROC is outside the outermost pole; stability additionally requires that the ROC contain the unit circle.

Table 13. Pole location and behaviour

Pole radius $ p $	Behaviour	Fixed-point implication
$ p < 1$	Decaying; stable	Accumulator bounded by $1/(1- p)$
$ p = 1$	Marginally stable (oscillator, integrator)	Accumulator grows without bound — needs explicit leakage or reset
$ p > 1$	Divergent	Unusable
$ p \rightarrow 1^-$	Very narrow band; long memory	Coefficient quantisation can push the pole outside — the classic failure mode of high-order direct-form IIR

Graduate · Quantifying the last row: for a direct-form IIR of order N , the sensitivity of pole p_i to a denominator coefficient a_k is $\partial p_i / \partial a_k = -p_i^{N-k} / \prod_{j \neq i} (p_i - p_j)$. The denominator is a product of *pole separations*: **clustered poles make the sensitivity explode**. Cascaded second-order sections avoid this because each section contains only one conjugate pair, so no small separations appear in its own denominator. This is the quantitative reason behind the universal practice of implementing high-order IIR filters as cascaded biquads, and it is worth being able to state it rather than merely follow it.

A2. Transforms and Spectral Representation

Table 14. The transform family

Transform	Domain	Kernel	Principal use in IP work
CTFT	continuous time $\rightarrow \omega$	$e^{-j\omega t}$	Analogue filter and antenna analysis
Laplace	continuous time $\rightarrow s$	e^{-st}	PLL loop dynamics, control, transmission lines
DTFT	discrete time $\rightarrow \omega$	$e^{-j\omega n}$	Theoretical filter response (continuous in ω)
DFT / FFT	finite sequence $\rightarrow$ bins	$e^{-j2\pi kn/N}$	Everything computable
Z	discrete time $\rightarrow z$	z^{-n}	Poles, zeros, stability, filter structures
Hilbert	real $\rightarrow$ analytic	$-j \operatorname{sgn}(\omega)$	I/Q generation, envelope, SSB
DCT	finite $\rightarrow$ cosine basis	$\cos$	Image/video coding (energy compaction)
Wavelet	time–scale	scaled basis	Transient detection, JPEG2000

A2.1 The DFT is not the DTFT

The DFT computes samples of the DTFT of a **windowed, periodically extended** sequence. Three artefacts follow, and all three appear as bugs in practice.

Table 15. DFT artefacts

Artefact	Cause	Symptom	Mitigation
Spectral leakage	Implicit rectangular window	A pure tone smears across bins	Apply a window (Hann, Blackman–Harris)
Scalloping loss	Tone falls between bin centres	Up to 3.9 dB amplitude error (rectangular)	Window, or interpolate the peak
Picket fence	Only N samples of a continuum	Frequency resolution limited to f_s/N	Zero-pad (interpolates, does not add resolution)
Circular convolution	Periodic extension	Wrap-around in fast convolution	Zero-pad to $N \geq L+M-1$

Zero-padding is routinely misdescribed as improving resolution. It does not. **Resolution is set by the observation time** $T = N/f_s$; two tones closer than $\approx 1/T$ cannot be separated no matter how many zeros are appended. Padding interpolates the displayed spectrum, which makes peaks easier to *locate* but not easier to *resolve*. In a specification, resolution and interpolation must be stated separately.

Table 16. Common windows

Window	Main-lobe width (bins)	First sidelobe	Use
Rectangular	2	−13 dB	Transient capture; maximum resolution
Hann	4	−31 dB	General purpose
Hamming	4	−41 dB	Slightly better near sidelobe
Blackman–Harris (4-term)	8	−92 dB	Spur hunting in converter test
Kaiser (β adjustable)	tunable	tunable	Design-to-spec
Flat-top	~9	−90 dB	Amplitude accuracy (calibration)

A2.2 Parseval, power spectral density, and dB conventions

$$\sum_n |x[n]|^2 = (1/N) \sum_k |X[k]|^2$$

Table 17. Decibel conventions that are routinely confused

Unit	Reference	Note
dB	ratio	10 log for power, 20 log for amplitude
dBm	1 mW	Absolute power
dBc	carrier	Spur levels, phase noise
dBFS	converter full scale	Digital level; not a physical power
dBm/Hz	1 mW per Hz	Spectral density; thermal floor -174 dBm/Hz @ 290 K
dBc/Hz	carrier per Hz	Phase noise $L(\Delta f)$

Graduate · A recurring measurement error is comparing a **single-bin** FFT magnitude with a **spectral density**. The FFT bin contains power integrated over the equivalent noise bandwidth of the window, which for a Hann window is 1.5 bins, not 1. Reporting “noise floor at -110 dBFS” without stating N , f_s and the window is not a measurement, because the number changes when any of the three changes. **Processing gain $10 \log_{10}(N/2)$ is often mistaken for converter performance.**

A3. Sampling, Reconstruction and Quantisation

A3.1 The sampling theorem and its practical corollaries

$$X_s(f) = f_s \sum_k X(f - k f_s)$$

Table 18. Sampling regimes

Regime	Condition	Where used	Hardware cost
Nyquist	$f_s > 2B$, base-band	Most baseband DSP	Anti-alias filter must be steep
Oversampling (OSR > 1)	$f_s \gg 2B$	$\Sigma\Delta$ converters, relaxed AAF	Quantisation noise spread over wider band: +3 dB SNR per doubling
Bandpass / under-sampling	$2f_H/n \leq f_s \leq 2f_L/(n-1)$	RF direct sampling receivers	Sampler analogue bandwidth must exceed f_H , not f_s
Time-interleaved	M converters at f_s/M	>10 GS/s ADCs (112G SerDes uses 32–64 way)	Offset / gain / timing skew mismatch creates spurs at kf_s/M

Graduate · **Time-interleaving is where the design house earns its fee.** An M -way interleaved ADC has three mismatch mechanisms, each producing a distinct spur family: offset mismatch gives tones at kf_s/M independent of input; gain mismatch gives sidebands at $kf_s/M \pm f_{in}$; timing skew gives the same sideband locations but with amplitude proportional to f_{in} . **The frequency dependence is the diagnostic:** sweep the input and see which spur grows. Digital background calibration of all three is a standard deliverable in a modern ADC-DSP receiver, and it is a *digital* block — which means a fabless digital IP vendor can sell it even though the converter itself is analogue. This is a concrete example of finding a sellable digital block adjacent to an analogue one you cannot build.

A3.2 Quantisation noise

$$SQNR_{dB} = 6.02 B + 1.76 + 10 \log_{10}(OSR)$$

Table 19. Where the ideal formula breaks

Effect	Mechanism	Consequence	Design response
Aperture jitter	Sampling instant uncertainty σ_t	$SNR = -20 \log_{10}(2\pi f_{in} \sigma_t)$	Dominates above ~1 GHz input; clock design becomes the ADC spec
Thermal noise	KT/C of sampling capacitor	Floors SNR regardless of bits	Increase C (costs power and bandwidth)
DNL / INL	Element mismatch	Harmonic distortion, missing codes	Calibration, dynamic element matching
Comparator meta-stability	Finite regeneration time	Rare large errors	More regeneration time or error detection
Correlated quantisation	Low-amplitude periodic input	Quantisation noise becomes tonal, not white	Dither — deliberately added noise to decorrelate

Graduate · The dither entry deserves emphasis because it is counter-intuitive: **adding noise improves the result.** Quantisation error is only white and signal-independent when the signal moves over many LSBs; for a small or slowly varying signal

the error becomes periodic and produces discrete tones, which are far more objectionable than an equivalent amount of broad-band noise (in audio they are audible; in a radar they look like targets). Subtractive dither — add a known pseudo-random sequence before quantising and subtract it after — removes the tones without the SNR penalty. **A dither generator is a small, precisely specifiable digital block and therefore exactly the kind of thing a one-person IP house can build and sell as part of a converter-adjacent package.**

A3.3 Reconstruction

Table 20. Reconstruction effects

Effect	Expression	Compensation
Zero-order hold droop	$\text{sinc}(f/f_s)$	−3.92 dB at Nyquist; pre-compensate with an inverse-sinc FIR
Image replicas	at $kf_s \pm f$	Reconstruction (anti-imaging) filter
Interpolation	up-sample then low-pass	Moves images away so the analogue filter can be gentle
Mismatch-shaping DAC	—	Pushes element mismatch error out of band; a digital technique for an analogue defect

A4. Probability, Random Processes and Noise

A4.1 Distributions that occur in hardware

Table 21. Distributions and where they arise

Distribution	Arises from	Appears in
Gaussian	Sum of many small independent effects (CLT)	Thermal noise, random jitter, process variation
Rayleigh	Magnitude of complex Gaussian	Fading envelope, noise magnitude
Rician	Complex Gaussian + deterministic component	Fading with line of sight
Poisson	Rare independent events	Shot noise, soft-error (SER) counts
Uniform	Quantisation residue (ideal)	Quantisation noise model
Exponential	Waiting time between Poisson events	Time between soft errors
Log-normal	Product of many factors	Shadowing, some reliability lifetimes
Weibull	Weakest-link failure	Oxide breakdown, reliability
Binomial	n Bernoulli trials	Bit errors in a block, yield
Chi-square	Sum of squared Gaussians	Energy detection, CFAR statistics

A4.2 Physical noise mechanisms

Table 22. Noise sources in silicon

Mechanism	Spectrum	Expression	Design lever
Thermal (Johnson)	White	$v_n^2 = 4kTR\Delta f$	Lower R; lower T; narrower band
Channel thermal (MOS)	White	$i_n^2 = 4kTyg_m\Delta f$	Higher g_m improves noise <i>figure</i> though noise power rises
Flicker (1/f)	1/f	$\propto K/(WLC_{ox}f)$	Larger devices ; chopping; auto-zeroing
Shot	White	$i_n^2 = 2qI\Delta f$	Present where carriers cross a barrier (junctions, photodiodes)
kT/C	Sampled	$v^2 = kT/C$	Independent of resistance ; only C helps
Substrate / supply coupling	Structured	—	Guard rings, separate supplies, differential design
Phase noise	$1/f^3$, $1/f^2$, flat	Leeson model	Higher Q, higher power, lower flicker

Graduate · Why flicker noise sets the architecture of precision analogue. $1/f$ noise is not reducible by filtering, because it lives at the frequencies where the signal of interest often lives (DC to kHz). The standard responses — chopping and auto-zeroing — both work by *moving the signal to a higher frequency where only white noise remains*, and both require digital support: a chopping clock, demodulation, and residual-ripple filtering. In a modern mixed-signal IP the digital half of that scheme is a well-defined block with a clean interface, and it is again a piece that a digital design house can own.

A4.3 Jitter and phase noise — the same thing in two languages

$$\sigma_t^2 = (1/(2\pi f_0)^2) \int 2 L(f) df$$

Table 23. Jitter taxonomy used in link specifications

Type	Symbol	Statistics	Cause	How it is separated
Random jitter	RJ	Gaussian, unbounded	Thermal, flicker	Fit tails of the bathtub curve
Deterministic jitter	DJ	Bounded	—	Peak-to-peak; decomposed below
Periodic	PJ	Sinusoidal	Supply coupling, spurs	FFT of the jitter sequence
Data-dependent	DDJ / ISI	Pattern-correlated	Channel loss	Compare per-pattern edge times
Duty-cycle distortion	DCD	Two-valued	Rise/fall asymmetry, threshold offset	Even/odd UI comparison
Bounded uncorrelated	BUJ	Bounded, random	Crosstalk	Statistical separation
Total jitter at BER	TJ(BER)	RJ⊗DJ convolution	—	$TJ = DJ + 2 \cdot Q(BER) \cdot RJ_{rms}$

Graduate · The last row is the one that appears in every SerDes specification, and the factor $Q(BER)$ is why: at $BER\ 10^{-12}$, $Q = 7.03$, so $TJ = DJ + 14.07\ RJ_{rms}$. **Random jitter is multiplied by fourteen.** This is why a small improvement in oscillator or phase noise is worth a large amount of design effort, and why jitter separation — distinguishing RJ from DJ in a measurement — is a required capability rather than a nicety. A modelling engineer asked to produce a link budget must implement this convolution correctly; adding RMS values in quadrature, which is the intuitive move, is wrong because DJ is bounded and does not add that way.

A4.4 Random processes

Table 24. Concepts and their use

Concept	Statement	Use in IP design
Stationarity (WSS)	Mean constant, autocorrelation depends on lag only	Precondition for spectral analysis
Ergodicity	Time average = ensemble average	Justifies measuring one long record instead of many devices
Wiener–Khinchin	PSD = FT of autocorrelation	Links time and spectrum
Markov chain	Memoryless state evolution	Bus arbitration analysis, FIFO occupancy, error models
Gauss–Markov	Correlated Gaussian	Coloured noise models
Cyclostationarity	Statistics periodic in time	All digitally modulated signals ; exploited for blind synchronisation
Point process	Random event times	Soft errors, packet arrivals

Graduate · Cyclostationarity is the theoretical basis for **blind** timing and carrier recovery: a modulated signal has periodically varying statistics at the symbol rate, so a suitable nonlinearity produces a spectral line at that rate even though the signal itself has no such line. Gardner and Mueller–Müller timing detectors are practical exploitations of this. Knowing the principle rather than the recipe is what lets an engineer design a detector for a modulation format that has no textbook detector — a situation that occurs constantly in proprietary links.

A5. Linear Algebra and Numerical Methods for Hardware

A5.1 Decompositions and their hardware character

Table 25. Matrix decompositions as IP blocks

Decomposition	Form	Cost	Streaming?	Numerical character
LU	$A = LU$	$n^3/3$	No (pivoting needs lookahead)	Needs pivoting for stability
Cholesky	$A = LL^*$	$n^3/6$	Yes	No pivoting needed for SPD; half the work of LU
QR (Givens)	$A = QR$	$2mn^2$	Yes	Backward stable; rotations are well conditioned
QR (Householder)	same	fewer ops	Less so	Best stability
SVD	$A = U\Sigma V^*$	iterative	No	Most robust ; reveals rank and conditioning
Eigen (symmetric)	$A = Q\Lambda Q^*$	iterative	No	Jacobi parallelises well
Schur / Hessenberg	—	n^3	No	Control applications

Graduate · The streaming column is the commercial column. Cholesky and Givens QR touch each input element once and can therefore be built with an `hls::stream`-style interface and no external memory; SVD and LU must revisit the array and therefore need an AXI master and a buffer. That single architectural difference changes the IP's integration story, its area, and its price. When a customer asks for “a matrix inverse block”, the first engineering question is whether the matrix is symmetric positive definite — because if it is, Cholesky gives a streaming solution at half the arithmetic, and if it is not, you are quoting a much larger block.

A5.2 Conditioning

$$\kappa(A) = \sigma_{\max}/\sigma_{\min} \quad \text{relative error} \lesssim \kappa(A) \cdot \epsilon_{\text{machine}}$$

Graduate · The rule of thumb that follows is directly usable: **you lose roughly $\log_{10}\kappa$ decimal digits**. In fixed point, substitute $\epsilon = 2^{-F}$ for F fractional bits and the statement becomes a word-length requirement: $F \gtrsim \log_2\kappa + (\text{bits of accuracy required})$. This is how a modelling engineer converts a mathematical property of the customer's data into a hardware parameter. It also explains why **iterative refinement** works: solve in low precision, compute the residual in high precision, correct, repeat. Each iteration roughly squares the accuracy, so three refinements from a rough start can reach near-full precision — but only if the condition number is modest, because κ enters the convergence factor. **Measured behaviour: for a well-conditioned (isotropic) system the scheme reached 24.2 bits of accuracy; at correlation 0.99 it reached only 12.4 bits**. An IP that advertises mixed-precision refinement must therefore state a conditioning limit, or it will fail at a customer whose data is correlated.

A5.3 Iterative solvers and their hardware mapping

Table 26. Iterative methods

Method	Update	Parallelism	Convergence
Jacobi	uses only previous iterate	Fully parallel	Slow; needs diagonal dominance
Gauss–Seidel	uses updated values immediately	Sequential within a sweep	Roughly twice Jacobi's rate
SOR	over-relaxed GS	Sequential	Tunable ω

Method	Update	Parallelism	Convergence
Conjugate gradient	Krylov subspace	Parallel (dot products)	n steps exactly; $\sqrt{k}$ in practice
Richardson	$x \leftarrow x + \alpha(b - Ax)$	Fully parallel	Simplest; α must be tuned

Graduate · There is a physical realisation worth knowing because it is repeatedly rediscovered and mis-described. An RC network that solves $C \, dv/dt = -(Av - b)$ settles to $A^{-1}b$, and is often presented as an “analogue Gauss–Seidel solver”. **It is not:** because all nodes evolve simultaneously from the same previous state, the continuous-time limit corresponds to **Jacobi / Richardson**, not Gauss–Seidel, which is defined by sequential in-sweep updates. The settling time is governed by $1/\lambda_{\min}$, i.e. by the condition number again. Under a normalisation that fixes $\lambda_{\max} = 1$, the measured settling-time-to-condition ratio was constant at 13.2 — the analogue solver buys constant factors, not asymptotic ones. **Being able to state this precisely prevents a design house from accepting a proposal whose speedup claim rests on a misidentification.**

B1. The MOSFET — What a Digital Designer Must Know

A digital IP engineer does not size transistors, but every timing number, every power figure and several verification hazards trace back to device behaviour. This chapter keeps only what changes decisions.

B1.1 Regions of operation

Table 27. MOSFET regions

Region	Condition	Current	Where it matters
Cut-off	$V_{GS} < V_{TH}$	$I_{sub} \propto e^{(V_{GS}-V_{TH})/nV_T}$	Subthreshold leakage — the dominant static power term below 65 nm
Triode / linear	$V_{DS} < V_{GS}-V_{TH}$	$\mu C_{ox}(W/L)[(V_{GS}-V_{TH})V_{DS} - V_{DS}^2/2]$	Switch resistance R_{on} ; pass gates; the ON device of an inverter at end of transition
Saturation	$V_{DS} > V_{GS}-V_{TH}$	$\frac{1}{2}\mu C_{ox}(W/L)(V_{GS}-V_{TH})^2(1+\lambda V_{DS})$	Analogue gain stages; the beginning of a digital transition
Velocity saturation	Short channel, high field	$\propto (V_{GS}-V_{TH})^1$ — linear, not square	Modern nodes live here. Textbook square-law intuition overestimates drive

Graduate · The last row is the single most important correction for anyone who learned the square law. In a short-channel device carriers reach their saturation velocity, so drive current becomes roughly proportional to overdrive rather than its square. Two practical consequences: **(i)** increasing supply voltage buys less speed than square-law intuition suggests, while dynamic power still rises as V^2 , so voltage scaling is a poor speed lever; **(ii)** stacking devices (as in a NAND with many inputs) costs more than the naive series-resistance estimate, which is why wide fan-in gates are avoided and logic is restructured into trees. When a synthesis tool reports that a 4-input gate is slower than two 2-input gates in series, this is why.

B1.2 Threshold voltage and its enemies

Table 28. V_{TH} modulation effects

Effect	Mechanism	Design consequence
Body effect	Source–bulk bias raises V_{TH}	Stacked devices are slower than expected
DIBL	Drain field lowers the barrier	V_{TH} falls with $V_{DS} \rightarrow$ more leakage
Random dopant fluctuation	Discrete dopant atoms	$\sigma_{V_{TH}} \propto 1/\sqrt{WL}$ — small devices mismatch more
Temperature	–1 to –2 mV/K	Hot chip is <i>faster</i> at low V_{DD} (temperature inversion)
NBTI / PBTI ageing	Trap generation under stress	V_{TH} drifts over years — timing must include an ageing margin
Multi- V_{TH} offering	Process option	LVT for critical paths, HVT elsewhere: the primary leakage-vs-speed lever

Graduate · **Temperature inversion is a verification trap.** At high supply voltage a chip is slowest when hot, so signing off at the high-temperature corner is conservative. At low supply voltage — which is where modern low-power modes operate — the V_{TH} reduction outweighs mobility degradation and the chip is slowest when **cold**. Teams that carried forward a "hot is

worst case" habit have taped out parts that fail at $-40\text{ }^{\circ}\text{C}$. The corner list is not a formality; it is a statement about which physics dominates in the operating region you are selling into.

B1.3 Scaling and what it stopped giving

Table 29. Dennard scaling and its breakdown

Quantity	Ideal scaling (factor $s > 1$)	What actually happened
Dimensions	$1/s$	Continued (with FinFET, GAA)
Supply V_{DD}	$1/s$	Stalled near 0.7–0.9 V — V_{TH} cannot follow without leakage explosion
Delay	$1/s$	Slower than ideal; interconnect does not scale
Power density	constant	Rose → dark silicon, thermal limits
Leakage	negligible	Comparable to dynamic below 65 nm
Interconnect RC	—	Worsens : resistance rises as cross-section shrinks

Graduate · The end of Dennard scaling is the reason the industry turned to **specialised accelerators**, and therefore the reason the IP business grew. When a single general-purpose core could no longer be made faster within a power budget, the way to get performance became putting the right fixed-function block next to the processor. **Every FEC, crypto, codec and NPU IP sold today exists because of this graph.** Understanding it lets a design house argue its value proposition in the customer's own terms: not "our block is fast", but "your general-purpose alternative costs x times the energy per operation".

B2. CMOS Logic, Delay and Power

$$t_{pd} \approx 0.69 R_{on} C_L$$

$R_{on} \propto 1/(W/L) \Rightarrow$ bigger device, faster, more input cap

FO4 = delay driving four identical inverters

— the technology-independent speed unit

Figure 4. The inverter, and the delay model every timing number ultimately rests on.

B2.1 Delay models

Table 30. Delay models by fidelity

Model	Form	Use
RC (Elmore)	$t_{pd} = 0.69 R_{on} C_L$	Hand estimates, intuition
Logical effort	$d = gh + p$	Optimal gate sizing and stage count without simulation
NLDM (lookup)	table over input slew $\times$ output load	Standard-cell STA
CCS / ECSM	current-source model	Advanced nodes, accurate slew propagation
SPICE	device equations	Characterisation, critical custom paths

Graduate · Logical effort is the one hand method worth memorising. With g the logical effort of a gate (1 for an inverter, 4/3 for NAND2, 5/3 for NOR2), h the electrical effort (fanout), and p parasitic delay, the path delay is minimised when **every stage carries equal effort** $f = (GH)^{1/N}$, and the optimal per-stage effort is ≈ 3.6 (≈ 4 in practice, whence "fanout-of-4"). This yields the optimal number of stages $N \approx \log_4(GH)$ directly. In an IP context it answers questions such as "how many buffer stages should the clock tree have?" or "is this 12-input decoder better as one stage or three?" before a single tool is run — which matters because those questions arise during architecture, when no netlist exists.

Graduate · FO4 as a unit. Quoting delay in FO4 units makes a design comparable across processes: a 30-FO4 pipeline stage is 30 FO4 whether the node is 130 nm or 5 nm. A measured data point for calibration: in the open SkyWater 130 nm PDK, an inverter chain with $W_p = 2.0 \mu\text{m}$, $W_n = 1.0 \mu\text{m}$, $L = 0.15 \mu\text{m}$ and $C_L = 6 \text{ fF}$ gives **FO4 $\approx 48 \text{ ps}$** (ngspice; stage delays 47.5 and 44.5 ps, rise time 67.9 ps). That implies a practical ceiling near **1 GHz** for a ~ 20 -FO4 pipeline stage in that process — which is the quantitative reason a 56 Gbd analogue decision loop is impossible there, and why an open-PDK project must choose a digital, sub-rate architecture.

B2.2 Power

$$P = \alpha C V_{DD}^2 f + I_{SC} V_{DD} + I_{leak} V_{DD}$$

Table 31. Power components and levers

Component	Driver	Lever	Cost of the lever
Dynamic (switching)	αCV^2f	Clock gating; reduce α by data gating; lower V_{DD}	Gating adds skew and verification states
Short-circuit	Both devices on during transition	Sharp input slews	Bigger drivers $\rightarrow$ more C
Subthreshold leakage	e^{-V_{TH}/nV_T}	HVT cells, power gating, body bias	Slower; wake-up latency; state retention
Gate leakage	Tunnelling through oxide	High- κ dielectric	Process choice, not design
Glitch power	Unbalanced arrival times	Balance logic depth ; pipeline	Area, latency

Graduate · Glitch power is an IP-level design decision that rarely appears in textbooks. In an unbalanced arithmetic tree, a node can toggle several times before settling, and each toggle costs full switching energy. Ripple-carry adders and unbalanced multiplier trees are notorious. Balancing the tree — or inserting a pipeline register that stops glitch propagation — can reduce datapath power by tens of percent at no functional cost. Because glitching is invisible in RTL simulation (it appears only in gate-level simulation with timing), it is systematically underestimated during architecture. **A design house that reports power measured from a back-annotated gate-level run, with the customer's own data pattern, differentiates itself from one that reports a synthesis estimate.**

B2.3 Logic families

Table 32. Logic styles

Style	Principle	Advantage	Why it is rarely used in IP
Static CMOS	Complementary pull-up/down	Robust, no clock, easy to verify	— the default
Transmission gate	Pass logic	Fewer devices for MUX/XOR	Threshold loss, charge sharing
Domino / dynamic	Precharge then evaluate	Fast, small	Noise-sensitive, needs custom timing ; not synthesisable
Pass-transistor (CPL)	—	Compact XOR	Level restoration needed
Current-mode (CML/ECL)	Differential current steering	Very high speed, constant current	Static power; used only in SerDes front ends
Adiabatic	Slow charge recovery	Low energy	Needs special clocks; niche

Graduate · A synthesisable IP is static CMOS by definition — everything else requires custom timing verification that a customer cannot repeat in their own flow. **This is a commercial constraint, not a technical preference.** The exception is the SerDes front end, where CML is unavoidable above a few GHz; that is precisely the part that is sold as a hard macro rather than RTL, and it is why the PMA/PCS boundary in a PHY falls where it does.

B3. Timing, Clocking and Static Timing Analysis

$$\text{Hold: } t_{cq} + t_{logic,min} \geq t_{hold} + t_{skew}$$

Setup fails $\Rightarrow$ slow the clock. Hold fails $\Rightarrow$ the chip is dead.

Figure 5. The two timing constraints. Setup limits frequency; hold limits correctness at any frequency.

B3.1 The two inequalities

$$T_{clk} \geq t_{cq} + t_{logic,max} + t_{setup} + t_{skew} + t_{jitter}$$

$$t_{cq,min} + t_{logic,min} \geq t_{hold} + t_{skew}$$

The asymmetry between the two is the single most important operational fact in digital timing. A setup violation is fixed by lowering the clock frequency, so a chip that fails setup still works, just slower. A hold violation has no frequency term: the chip is **broken at every frequency** and the only remedy is a mask change. Consequently hold is fixed exhaustively before tape-out, by buffer insertion, while setup is traded against performance targets. In IP delivery this means the constraint file (SDC) you ship must make the customer's hold analysis possible — omitting clock definitions or false-path declarations can cause a customer to close hold on a path that does not exist, or worse, to miss one that does.

B3.2 Clock distribution

Table 33. Clock network structures

Structure	Skew	Power	Use
H-tree	Low by symmetry	High	Regular arrays, large blocks
Buffered tree (CTS)	Tool-balanced	Moderate	Standard ASIC flow
Mesh / grid	Very low	Very high	High-performance CPUs
Spine + local trees	Moderate	Moderate	Common compromise
Useful skew	Deliberately non-zero	—	Borrow time from a fast stage to a slow one

Graduate · **Useful skew (clock borrowing)** is worth knowing because it turns a timing failure into a scheduling problem. If stage A has slack and stage B does not, delaying B's launch clock moves margin from A to B. The tool does this automatically, but the consequence for an IP vendor is subtle: **a block whose internal paths are already borrowing has little tolerance for the customer's clock tree**. Reporting timing with an assumed skew budget, and stating that budget explicitly in the datasheet, prevents the integration failure where the block meets timing in the vendor's flow and misses it in the customer's.

B3.3 What STA cannot see

Table 34. Limits of static timing analysis

Issue	Why STA misses it	What catches it
False paths	STA is structural, not functional	Designer-declared exceptions — and a wrong declaration hides a real path
Multicycle paths	Same	Declaration plus functional verification
Asynchronous cross-ings	No single clock relation	CDC static analysis , not STA
Metastability	Probabilistic, not deterministic	MTBF calculation; synchroniser depth
Glitches	STA reports arrival, not toggle count	Gate-level power simulation
Crosstalk-induced delay	Depends on aggressor timing	SI-aware STA (signal-integrity mode)
IR drop	Voltage assumed constant	Power/IR co-analysis
On-chip variation	Single delay per cell	OCV / AOCV / POCV derating

Graduate · **Exception declarations are the most dangerous artefact in a timing constraint file**. Each `set_false_path` removes a path from analysis; if the declaration is wrong, that path is simply never checked and the failure appears only in silicon. A mature IP deliverable therefore ships its SDC with a written justification for every exception, and ideally with an assertion or formal property that proves the path is genuinely unexercisable. **This is a place where a modelling engineer contributes directly: the argument that a path cannot be sensitised is a functional argument, and the person who wrote the reference model is usually the one who can make it.**

B3.4 Metastability quantified

$$MTBF = e^{t_r/\tau} / (T_0 f_{clk} f_{data})$$

Graduate · The exponential in t_r (resolution time allowed) is why adding one synchroniser stage improves MTBF by orders of magnitude rather than by a factor of two. With typical 28 nm flip-flop parameters ($\tau \approx 20$ ps), one extra stage at 1 GHz multiplies MTBF by $e^{1000/20} = e^{50}$ — an astronomically large factor. The corollary is that **two stages is almost always enough and three is almost always superstition**, except at very high clock rates where t_r per stage is small. Being able to compute this rather than follow a rule is what lets an IP vendor justify a latency budget to a customer who wants the crossing to be faster.

B4. Interconnect, Transmission Lines and Signal Integrity

Below roughly 250 nm, wires stopped being ideal connections and became circuit elements. Above a few GHz they stop being lumped elements and become transmission lines. Both transitions change what a designer must do.

B4.1 On-chip interconnect as distributed RC

$$t_{\text{delay}} \approx 0.38 R_w C_w L^2 \quad (\text{distributed RC line of length } L)$$

Table 35. Interconnect scaling and its remedies

Problem	Cause	Remedy	Cost
Delay grows as L^2	Distributed RC	Repeater insertion → delay becomes linear in L	Power and area; repeaters can be 30% of a large SoC's dynamic power
Resistance rises with scaling	Smaller cross-section, surface scattering	Thicker upper metal layers for global routes	Fewer routing tracks
Coupling capacitance dominates	Tall narrow wires, close spacing	Increase spacing; shield with ground lines	Routing area
Electromigration	Current density in narrow wires	Width rules, current limits	Area; constrains power grid design
IR drop	Resistance of the power grid	Grid density, decoupling capacitance	Metal resources

Graduate · **Optimal repeater insertion** follows from minimising the total delay of a line broken into k segments each driven by a repeater of size h . The classic result is that the optimum makes the repeater's intrinsic delay comparable to the wire segment delay, giving $k_{\text{opt}} = L\sqrt{(R_w C_w)/(2R_0 C_0)}$. The practical consequence for an IP vendor is that **a block's timing cannot be guaranteed independent of its physical size**: a 2 mm-wide block has internal wire delays that a synthesis-only estimate will miss entirely. This is why serious IP deliverables include a floorplan hint or a hardened layout, and why "it met timing in synthesis" is not a claim a customer will accept for a large block.

B4.2 When a wire becomes a transmission line

Undergraduate review · A connection must be treated as a transmission line when its electrical length is a significant fraction of the signal's wavelength — in practice when the propagation delay exceeds roughly one tenth of the signal rise time. Since t_r shrinks with every process generation, the threshold length keeps falling.

$$Z_0 = \sqrt{L/C} \quad v_p = 1/\sqrt{LC} = c/\sqrt{\epsilon_r} \quad \Gamma = (Z_L - Z_0)/(Z_L + Z_0)$$

Table 36. Transmission-line effects in a link

Effect	Physical cause	Frequency behaviour	Consequence
Conductor (skin) loss	Current crowds into a skin depth $\delta \propto 1/\sqrt{f}$	$\propto \sqrt{f}$	Dominant loss below ~20 GHz on PCB
Dielectric loss	$\tan\delta$ of the substrate	$\propto f$	Dominant at high frequency; chooses the laminate

Effect	Physical cause	Frequency behaviour	Consequence
Reflections	Impedance discontinuities (vias, connectors)	Resonant dips	Return loss; creates ISI that FFE cannot fully fix
Crosstalk (NEXT/FEXT)	Mutual L and C between traces	Rises with f	Limits lane density
Fibre weave effect	Inhomogeneous ϵ_r of woven glass	—	Skew between differential pair halves
Mode conversion	Asymmetry in a differential pair	—	Differential energy becomes common mode → EMI

Graduate · Why skin effect makes channel loss go as $\sqrt{f}$ and why that shapes the equaliser. Skin depth $\delta = \sqrt{2\rho/\omega\mu}$ shrinks as $1/\sqrt{f}$, so the effective conductor cross-section shrinks and resistance rises as $\sqrt{f}$. The resulting channel magnitude response is approximately $\exp(-k\sqrt{f})$, which in the time domain produces a **long, slowly decaying pulse tail** rather than a sharp one. That specific tail shape is why decision-feedback equalisation works so well on wireline channels: the post-cursor ISI is long but the symbols causing it have already been decided, so they can be subtracted exactly without noise enhancement. **The physics of the conductor selects the equaliser architecture.** An engineer who knows only that "DFE cancels post-cursor ISI" cannot explain why a different channel — say a multipath radio channel with pre-cursor energy — needs a different structure.

B4.3 S-parameters

Table 37. Scattering parameters for a two-port

Parameter	Meaning	Specification name
S_{11}	Input reflection	Return loss (dB, negative is good)
S_{21}	Forward transmission	Insertion loss
S_{12}	Reverse transmission	Isolation
S_{22}	Output reflection	Output return loss
S_{dd}, S_{cc}	Differential / common mode	Mixed-mode S-parameters
S_{cd}, S_{dc}	Mode conversion	Asymmetry metric — an EMI predictor

Graduate · S-parameters are used because at high frequency you cannot measure voltage and current at a port without perturbing it, but you can measure incident and reflected power waves. For a modelling engineer the practical point is the **conversion to a time-domain model**: a channel is delivered as a Touchstone (.s4p) file, and a link simulation needs its pulse response. Doing that conversion correctly requires enforcing **causality and passivity** on measured data that generally violates both because of measurement noise and band limitation. Non-causal channel models produce link simulations that are optimistic in a way that is very hard to notice. **A channel-model conditioning tool is a small, genuinely sellable piece of software**, and it is squarely modelling-team work.

B4.4 Power delivery and simultaneous switching noise

$$V_{noise} = L_{package} \cdot dI/dt + R_{grid} \cdot I$$

Table 38. Power integrity mechanisms

Mechanism	Where	Mitigation
Static IR drop	On-chip grid resistance	Grid density, more straps
dI/dt noise (SSN)	Package and board inductance	Decoupling capacitance at three levels: on-die, package, board
Resonance	L_{pkg} with on-die C	Anti-resonance peak typically 50–200 MHz ; add damping
Ground bounce	Shared return inductance	More ground pins, differential IO
Supply-induced jitter	V_{DD} modulates delay	Regulate locally; use supply-insensitive delay cells in clock paths

Graduate · Supply-induced jitter is the mechanism by which a *digital* design decision damages an *analogue* specification. A large synchronous block that starts and stops — a clock-gated accelerator, a burst-mode FEC decoder — produces a current step at the burst rate, which modulates the supply, which modulates the delay of the PLL's delay cells, which appears as a spur in the phase noise, which appears as periodic jitter (PJ) in the link budget. **The FEC block is the root cause of a jitter specification failure**, and nothing in either block's own verification would reveal it. This class of cross-domain coupling is why chip-level power-aware simulation exists, and why an IP datasheet should state the block's *current profile*, not merely its average power.

B5. Analogue Building Blocks

A digital IP house does not design these, but it must model them, specify them, and understand which digital block can compensate which analogue imperfection — because that compensation is often the sellable part.

B5.1 Amplifiers

Table 39. Amplifier topologies

Topology	Gain	Bandwidth	Where used
Common source	$-g_m r_o$	Moderate	Basic gain stage
Cascode	$-g_m (g_m r_o) r_o$	High (reduced Miller)	High-gain stages
Differential pair	—	—	Rejects common-mode noise ; the basis of nearly everything
Folded cascode	High	Good	Wide input range op-amps
Two-stage Miller	Very high	Compensated	General-purpose op-amp
CTLE	peaked	—	Source degeneration creates a zero that boosts high frequency
TIA	$-R_f$	—	Photodiode front end

Graduate · Why a CTLE amplifies noise and an FFE does not have to. A CTLE is a linear analogue filter placed *before* the point where noise is added by the rest of the receiver, but *after* the channel has already attenuated the signal and after thermal noise from the channel and the front end. Boosting high frequency therefore boosts the noise already present in that band by the same factor. A digital FFE placed after the ADC has exactly the same problem. **ADFE** escapes it because it subtracts a *decided* symbol — a noiseless quantity — rather than amplifying a received one. This is the whole reason receivers combine a modest CTLE with a DFE instead of using a large CTLE alone, and it is a piece of reasoning that a modelling engineer must be able to reproduce when asked to justify an architecture.

B5.2 Comparators and references

Table 40. Comparator and reference issues

Block	Key imperfection	Digital compensation
Strong-arm latch	Input-referred offset (mismatch)	Offset calibration DAC trimmed digitally
	Metastability when inputs are close	Allow regeneration time; detect and flag
	Kickback onto the input	Sample-and-hold isolation
Bandgap reference	Curvature over temperature	Piecewise digital trim
	Start-up failure mode	Start-up circuit plus watchdog
Current DAC	Element mismatch	Dynamic element matching (digital)

Graduate · Each row's right-hand column is a digital block with a clean specification, and that is the commercial observation: **the calibration and trim logic around an analogue block is frequently larger than the analogue block itself, and it is synthesisable**. A design house that cannot build a comparator can still own the offset-calibration engine, the DEM scrambler, and the background interleaving-mismatch corrector. These are sold as part of converter IP, and they are where the modelling effort concentrates because their correctness is statistical rather than logical.

B5.3 PLLs and clock generation

$$H(s) = K_{PD}K_{VCO}F(s) / (s + K_{PD}K_{VCO}F(s)/N)$$

Table 41. PLL noise transfer

Noise source	Transfer to output	Design implication
Reference noise	Low-pass ($\times N$ in band)	In-band noise is multiplied by $20 \log_{10} N$
VCO noise	High-pass	Wide loop suppresses VCO noise
Divider noise	Low-pass	—
Charge-pump noise	Low-pass	Dominates in-band floor
$\Sigma\Delta$ quantisation (fractional-N)	High-pass shaped	Loop must be narrow enough to filter it

Graduate · The opposing shapes create the **optimal loop bandwidth**: wide enough to suppress VCO phase noise, narrow enough to suppress reference and fractional- N quantisation noise. The optimum is where the two contributions cross. This is a genuinely quantitative design decision that a system modeller can and should compute, and it is directly connected to the link jitter budget of Chapter A4 — the integrated phase noise becomes the RJ term that is multiplied by 14 at 10^{-12} BER. **Chapters A4, B4 and B5 are three views of the same budget**, and one of the marks of a senior engineer is holding them together.

B5.4 Data converters

Table 42. ADC architectures

Architecture	Speed	Resolution	Principle	Digital support needed
Flash	Highest	≤ 6 bit	$2^N - 1$ comparators	Thermometer $\rightarrow$ binary, bubble correction
SAR	Moderate–high	8–14 bit	Binary search with a DAC	Redundancy and digital error correction
Pipeline	High	10–14 bit	Stages with residue amplification	Inter-stage gain calibration
$\Sigma\Delta$	Low–moderate	16–24 bit	Oversample and noise-shape	Decimation filter (CIC + FIR)
Time-interleaved SAR	>10 GS/s	6–8 bit	M SARs in parallel	Offset/gain/skew background calibration — the 112G receiver case
Folding/interpolating	High	8–10 bit	Reduce comparator count	—

Graduate · **$\Sigma\Delta$ noise shaping** is worth stating exactly because it is the clearest example of trading bandwidth for resolution. An L th-order modulator with oversampling ratio OSR gives SNR gain $\approx (6L+3)$ dB per doubling of OSR, versus 3 dB for plain oversampling. The price is that the modulator output is a low-resolution, very fast stream that must be decimated — and **that decimation filter is a substantial digital IP block** whose passband ripple and stopband attenuation determine the converter's final specification. A converter vendor's datasheet number is in part a statement about a digital filter. This is the second time in this chapter that the saleable digital block sits next to an analogue one.

C1. Arithmetic Units — The Core of Every Datapath

C1.1 Addition

Same function. Five points on the area–delay curve.

Figure 6. Adder architectures span an area–delay curve of roughly an order of magnitude in each axis.

Table 43. Adder architectures

Architecture	Delay	Area	Notes
Ripple carry	$O(n)$	$O(n)$	Baseline; fine for $n \leq 8$ at low frequency
Carry-skip	$O(\sqrt{n})$	$O(n)$	Cheap improvement
Carry-select	$O(\sqrt{n})$	$\sim 2\times$	Duplicate blocks, select on carry
Carry-lookahead	$O(\log n)$	$O(n \log n)$	Classic
Kogge–Stone	$O(\log n)$	Large, heavy wiring	Minimum depth; wire-limited in practice
Brent–Kung	$O(\log n)$	Fewer wires	Depth $2 \log n$; better area
Carry-save	$O(1)$ per add	$O(n)$	Does not propagate carry — the key to fast multipliers and accumulators

Graduate · **Carry-save is the single most useful idea in this table.** A carry-save adder takes three operands and produces two (sum and carry vectors) in constant time, because no carry propagates. A chain of them accumulates many terms at constant delay per term, and only the *final* conversion to a normal binary number requires a carry-propagate adder. This is why multiplier trees, FIR accumulators, and MAC units are built as "compress many partial products with carry-save, then one fast adder at the end". **In an accumulation loop — the feedback path that limits every recursive filter — keeping the state in carry-save form removes the carry-propagate delay from the loop entirely.** That single transformation has rescued more timing-critical datapaths than any other.

C1.2 Multiplication

Table 44. Multiplier construction

Stage	Technique	Effect
Partial product generation	Booth radix-4	Halves the number of partial products; needs 2's-complement handling
	Booth radix-8	Fewer still, but needs a 3× multiple (extra adder)
Reduction	Wallace tree	$O(\log n)$ depth, irregular layout
	Dadda tree	Slightly fewer adders than Wallace
	Array	Regular layout, $O(n)$ depth
Final add	Fast carry-propagate adder	Kogge–Stone or similar
Whole unit	Pipelining	Cut the tree with registers to raise $f_{\max}$

Graduate · **Constant multiplication is a different problem** and is worth separating in any specification. When one operand is a compile-time constant — filter coefficients, twiddle factors, scaling constants — the multiplier collapses into shifts and adds. Canonical signed digit (CSD) representation minimises the number of non-zero digits, and **multiple constant multiplication (MCM)** algorithms share sub-expressions across a whole coefficient set. For a 32-tap FIR with fixed coefficients this routinely gives a 3–5× area reduction over generic multipliers. The commercial point: **an IP that is parameterised for run-time coefficients cannot use this, so "programmable coefficients" is an expensive feature** that should be priced and specified as such, not thrown in because it seems flexible.

C1.3 Division, square root, and reciprocal

Table 45. Division approaches

Method	Convergence	Hardware	Use
Restoring / non-restoring	1 bit per cycle	Adder + shifter	Small area, high latency
SRT (radix-4/8)	2–3 bits per cycle	Lookup for quotient digit	Standard in FPUs
Newton–Raphson	Quadratic (doubles digits)	Multipliers	Reuses the multiplier; good when one exists
Goldschmidt	Quadratic	Multipliers	Better pipelining than Newton
Reciprocal LUT + refine	—	Small ROM + multiplier	The usual answer in DSP

The most important division fact for an IP designer is architectural, not numerical: never put a divider in a feedback loop. Its latency enters the loop directly and sets the initiation interval. The standard transformation is to compute a reciprocal *once* outside the loop and multiply inside it. The Cholesky decomposition is a textbook example — the diagonal reciprocal is formed once per column and the column is then scaled by multiplication, which is why the inner loop can be pipelined at $II = 1$. This is also a place where the reference model and the RTL can legitimately differ: the model may divide, the RTL multiplies by a reciprocal, and the two agree only to within the reciprocal's rounding. **The specification must state which one is normative.**

C1.4 Fixed-point and floating-point units

Table 46. Number format decisions

Format	Range	Hardware cost	Where it belongs
Fixed point $Q_{m.n}$	Limited, uniform	Adder/multiplier only	Most DSP and comms datapaths
Block floating point	Shared exponent per block	Small extra	FFT, where dynamic range grows predictably

Format	Range	Hardware cost	Where it belongs
IEEE 754 binary32	Wide	Align, normalise, round — expensive	Scientific, some solvers
binary16 / bfloat16	Wide, low precision	Cheaper	Neural inference
Integer with saturation	Limited, clamped	Compare and clamp	Where wrap would be catastrophic (LLRs, audio)
Posit / logarithmic	Tapered	Unusual	Research; rarely in shipped IP

Graduate · **Block floating point deserves more attention than it gets.** In an FFT the signal magnitude grows by up to a factor of two per stage. Full floating point is overkill; fixed point requires either wide words or per-stage scaling that loses SNR. Block floating point keeps one exponent per stage (or per block) and normalises once, recovering most of floating point's dynamic range at a small fraction of the cost. **For a modelling engineer this format is a trap**, because a naive floating-point reference model will not match the hardware's block-normalised behaviour bit for bit — the reference must model the normalisation decisions too. Specifying "bit-accurate reference model" without specifying the scaling policy produces months of false mismatches.

C2. Control: State Machines, Pipelines and Flow Control

C2.1 FSM encoding

Table 47. State encodings

Encoding	Re-gisters	Next-state logic	When
Binary	$\log_2 N$	Complex	Many states, area critical
Gray	$\log_2 N$	Complex	Adjacent states differ by one bit — low power, safer across CDC
One-hot	N	Simple (one AND per transition)	FPGA default ; fast; easy to check
Johnson	$N/2$	Simple	Counters, ring sequencers
Hamming-protected	$>\log_2 N$	—	Safety/security : illegal states detectable

Graduate · **Security-grade FSM encoding** is a concrete example of a requirement that comes from a threat model rather than from function. If an attacker can flip a state bit with a laser or a voltage glitch, a binary-encoded FSM may land in a valid but wrong state — for instance skipping rounds of a cipher. Countermeasures are: sparse encodings with large Hamming distance so that a single flip lands in an illegal state; a default branch that raises an alarm rather than doing nothing; and **duplicated FSMs with complementary encodings** whose outputs must remain complementary. The last technique requires a synthesis barrier so the tool does not optimise the inverters away and merge the two copies — if it does, the redundancy disappears while *functional verification still passes*. That silent failure mode is the reason such designs contain explicit buffer primitives whose only purpose is to stop the optimiser.

C2.2 Pipelining and its hazards

Table 48. Pipeline transformations

Transformation	What it does	Cost	Limit
Pipelining	Insert registers between logic stages	Latency, area	Cannot cut a feedback loop
Retiming	Move existing registers across logic	None (if legal)	Total registers on each loop is invariant
Loop un-rolling	Process k iterations per cycle	$k \times$ area	The loop's critical path is divided by k only in the feedforward part
Speculation	Compute all outcomes, select afterwards	Exponential in the number of speculated bits	Removes the decision from the loop
C-slow	Interleave k independent streams	Registers $\times k$	Needs k independent problems
Algebraic transform	Restructure the recurrence itself	Design effort	The only way past a fundamental loop bound

Graduate · **The iteration bound** is the hard limit that these transformations negotiate with. For a recursive system, the minimum achievable iteration period is $T_\infty = \max_{\text{loops}} (t_{\text{loop}}/w_{\text{loop}})$, where t_{loop} is the total computation delay around a loop

and w_{loop} the number of registers in it. Retiming and pipelining cannot beat it; only changing the recurrence can. Recognising this quantity turns a vague "we need more speed" into a specific question: *which loop, and can its algebra be rewritten?* Look-ahead transformation (computing two steps of a recurrence in one) doubles w and thereby halves T_{∞} , at the cost of more arithmetic. **This is the abstract form of the unrolled DFE, radix-4 Viterbi ACS, and reformulated Berlekamp-Massey — three blocks that look unrelated and are the same transformation.**

C2.3 Flow control and backpressure

Table 49. Handshake styles

Style	Signals	Property	Hazard
Valid only	valid	Producer never stalls	Consumer must always accept — needs guaranteed rate
Valid/Ready	valid, ready	Full backpressure	Combinational loop if ready depends on valid
Credit-based	credits returned	Decouples latency from throughput	Credit accounting bugs
Req/Ack (4-phase)	(4- handshake pairs)	Async-safe	Slow (two round trips)

The valid/ready combinational loop is one of the most common integration failures in modular RTL. If module A's ready depends combinationaly on its input valid, and module B's valid depends combinationaly on its input ready, connecting them creates a zero-delay cycle. Each module is individually correct and passes its own tests. The standard remedies are a *skid buffer* (also called a spill register), which breaks the path at the cost of one register stage and one entry of buffering, or a rule that ready is registered. **An IP that documents which of its interfaces are combinationaly coupled — and ships a skid buffer — saves its customers a week each.** This is exactly the kind of detail that distinguishes a product from a piece of code.

C2.4 Arbitration

Table 50. Arbiter types

Type	Fairness	Latency	Use
Fixed priority	None (starvation possible)	Lowest	Strict QoS classes
Round robin	Fair	Low	General purpose
Weighted round robin	Proportional	Low	Mixed traffic classes
Matrix / LRU	Fair, true least-recently-used	Higher	Caches
Lottery	Statistical	Low	Rare
Age-based	Strict FIFO fairness	Higher	Avoids starvation strictly

Graduate · Arbitration is where **fairness and forward progress** become formal properties rather than intentions. A round-robin arbiter is fair by construction; a fixed-priority arbiter is not, and a low-priority requester can starve forever. Whether starvation matters is a system question — it is acceptable for a debug port, fatal for a DMA that feeds a real-time codec. Because starvation is a *liveness* property ("eventually granted") rather than a safety property, it is natural to express and prove with formal tools, and arbiters are one of the few places where formal verification is both easy and genuinely valuable. **Shipping a formally proven arbiter with its properties is a differentiator that costs a design house little.**

C3. Clock Domain Crossing, Reset and Low Power

C3.1 The CDC problem stated precisely

Undergraduate review · A signal crossing between unrelated clock domains violates setup or hold at the receiving flip-flop with non-zero probability. The flip-flop may enter a metastable state whose resolution time is unbounded (though exponentially unlikely to be long). **This cannot be simulated:** a logic simulator has no metastable value and will always resolve to 0 or 1.

Table 51. CDC techniques by payload type

Payload	Technique	Why	Failure if misapplied
1-bit level	Two-flop synchroniser	Allows a full cycle to resolve	—
1-bit pulse	Toggle synchroniser (level convert, then edge detect)	A pulse shorter than the destination period would be lost	Lost events
Multi-bit, unrelated	Synchronise a request; use a data hold register	Bits arriving in different cycles corrupt the value	Corrupted data words
Multi-bit counter	Gray code	Only one bit changes per increment	Wrong pointer → FIFO corruption
Stream	Asynchronous FIFO (Gray pointers, dual-port RAM)	Decouples rate and phase	—
Bus transaction	Handshake (req/ack) or credit	Explicit acknowledgement	—
Reset	Asynchronous assert, synchronous de-assert	De-assertion must not violate recovery/removal	Part of the design leaves reset a cycle late

Graduate · Why Gray coding a FIFO pointer is safe even though the pointer is multi-bit. The synchroniser may sample a Gray pointer mid-transition, but since only one bit changes per increment, the sampled value is either the old or the new pointer — never a third value. An off-by-one pointer makes the FIFO report itself slightly *fuller* or *emptier* than it is, which is conservative: the FIFO may stall a cycle early but never overflows or underflows. **The design is safe because its error mode is biased in the harmless direction.** This principle — arrange for uncertainty to fail conservatively — generalises far beyond FIFOs and is one of the most transferable ideas in digital design.

C3.2 Reset architecture

Table 52. Reset strategies

Strategy	Advantage	Problem
Synchronous	No recovery/removal issue; clean STA	Needs a running clock — fails at power-up
Asynchronous	Works without a clock	De-assertion can violate recovery
Async assert, sync de-assert	Both advantages	Requires a reset synchroniser per domain — the standard solution
Reset-less registers	Area and routing saving	Must be provably initialised by data flow; a verification obligation

Reset de-assertion order is a specification item that is almost always omitted. If two blocks leave reset in different cycles and one samples the other's outputs, the receiving block may latch garbage. Within a block the designer controls this; across an IP boundary the *customer* controls it, and they cannot get it right unless the datasheet states the requirement. A good IP datasheet specifies: the reset polarity, whether it is synchronous or asynchronous, the minimum assertion width in cycles of each clock, and any required ordering between multiple resets. **Omitting this produces intermittent bring-up failures that are blamed on the IP.**

C3.3 Low power design

Table 53. Power reduction techniques by level

Level	Technique	Saving	Verification burden
RTL	Clock gating	Large (clock tree is 20–40% of dynamic power)	Low — tools insert it automatically
RTL	Operand isolation / data gating	Moderate	Low
RTL	Reduce switching activity (encoding, bus inversion)	Moderate	Low
Architecture	Parallelism + voltage scaling	Large — power $\propto V^2$	Moderate
Architecture	Memory hierarchy (avoid far accesses)	Large	Moderate
Physical	Multi- V_{TH} cells	Leakage	None
System	Power gating	Leakage $\rightarrow \sim 0$	High: isolation, retention, wake sequencing
System	DVFS	Large	High: timing at every operating point
System	Multiple power domains	Large	Highest: UPF, isolation cells

Graduate · Parallelism as a power technique is the least intuitive entry and the most powerful. Two copies of a block running at half the clock frequency deliver the same throughput; because they now have twice the time budget, the supply voltage can be lowered until the slower path just meets timing. Dynamic power scales as V^2f , so halving f and reducing V by, say, 30% gives roughly $0.5 \times 0.49 = 0.25$ of the original power, at the cost of about twice the area. **This trade — area for energy — is the fundamental reason accelerators are more efficient than processors**, and it is the argument an IP vendor uses when selling a block against a software implementation. State it with the exponents and it is persuasive; state it as "our block is more efficient" and it is not.

C3.4 Design for test

Table 54. DFT structures

Structure	Tests what	Cost	IP implication
Scan chains	All flip-flops and combinational logic	Mux in every FF (~5–10% area, some delay)	IP must be scan-insertable: no gated clocks without test bypass, no latches, no async loops
MBIST	Embedded memories	Controller per memory group	Memory interfaces must be accessible
BSD (JTAG 1149.1)	Board-level interconnect	Boundary cells	—

Structure	Tests what	Cost	IP implication
LBIST	Logic, in-field	PRPG + MISR	Automotive/safety
ATPG coverage	—	—	Stuck-at >99%, transition >90% typical targets
Test compression	—	Decompressor/compactor	Reduces tester time and cost

Scan is a security hole. A scan chain can read and write every flip-flop in the design, including key registers. Production chips must therefore disable scan after manufacturing test, typically by blowing a fuse or advancing a life-cycle state. A security IP that does not document its scan-isolation requirement will be integrated insecurely. **Conversely, an IP that cannot be scanned at all is unsellable**, because the customer cannot achieve their test coverage target. The resolution — scannable, but with key registers excluded from the chain or cleared on scan entry — must be designed in, and it is a requirement that comes from neither function nor timing.

D1. Instruction Set Architecture

An ISA is a contract between hardware and software. For a modelling engineer it is the *specification document* in the most literal sense: the reference model **is** the ISA, written executably.

Table 55. ISA design axes

Axis	Options	Consequence for hardware
Operand model	Stack / accumulator / register-memory / load-store	Load-store simplifies pipelining; every RISC uses it
Instruction length	Fixed / variable / compressed	Fixed simplifies fetch; compressed (RVC, Thumb) saves 25–30% code size at the cost of alignment logic
Addressing modes	Few / many	Many modes need an address generation unit; few modes need more instructions
Condition handling	Flags / compare-and-branch	Flags create a serialising dependency ; RISC-V deliberately has none
Delay slots	Present (classic MIPS) / absent	Delay slots expose the pipeline in the ISA — a design mistake later reversed
Register count	8 / 16 / 32 / more	More registers reduce spills but widen every instruction field
Exceptions	Precise / imprecise	Precise exceptions constrain the whole microarchitecture

Graduate · Delay slots are the canonical example of leaking microarchitecture into architecture. MIPS exposed its single branch-delay slot so that the compiler could fill it, saving a stall in a five-stage pipeline. When later implementations had deeper pipelines and branch prediction, the delay slot became useless baggage that every implementation still had to honour. **The lesson for IP design generalises: a specification that encodes today's implementation constrains tomorrow's.** When writing a block's interface, ask which parts describe *what* and which describe *how*, and expose only the former.

Graduate · Precise exceptions mean that when an exception is taken, all instructions before it have completed and none after it has had any effect. This is what makes an ISS a valid reference: the model can execute one instruction at a time and still describe a machine that executes many concurrently. Achieving it in an out-of-order machine requires a reorder buffer and speculative state, which is a large fraction of such a core's complexity. **The entire step-and-compare verification methodology rests on precise exceptions**; without them there would be no well-defined point at which model and RTL should agree.

D1.2 RISC-V as a case study

Table 56. RISC-V structure

Element	Content	Modelling note
Base integer	RV32I / RV64I — ~40 instructions	Small enough to model exhaustively
M	Multiply/divide	Division by zero is defined , not trapping
A	Atomics (LR/SC, AMO)	Requires a memory consistency model
F/D/Q	Floating point	IEEE 754; needs SoftFloat, not host arithmetic
C	Compressed 16-bit	Alignment: instructions may straddle a word
V	Vector	Vector-length agnostic — a model must track <code>v1</code> , <code>vtype</code>
B, Zk, Zc...	Bit manipulation, crypto, code size	—

Element	Content	Modelling note
Privileged	M/S/U modes, CSRs, PMP, virtual memory	Where most model bugs live: exception priority and CSR side effects

Exception priority is the most common source of reference-model defects in a CPU project. One instruction can simultaneously satisfy the conditions for several exceptions — misaligned address, page fault, access fault, breakpoint. The specification gives a strict priority order. A model that implements a different order is correct on almost every test and wrong on a narrow class of inputs that constrained-random stimulus may take weeks to find. The remedy is not more random testing but **directed tests derived from the priority table itself:** enumerate the table, construct one case per row, and check. This is a half-day of work that reliably finds bugs a month of random testing misses.

D2. Pipelining, Hazards and Speculation

Throughput 1 instr/cycle; latency 5 cycles

hazards: structural · data · control

Forwarding removes most data hazards; load-use needs one stall

Control hazards cost the branch penalty × misprediction rate

Figure 7. The classic five-stage pipeline and its three hazard classes.

Table 57. Hazards and remedies

Hazard	Cause	Remedy	Residual cost
Structural	Two instructions need the same resource	Duplicate the resource, or stall	Area
Data RAW	Read after write	Forwarding from EX/MEM	Load-use still costs one cycle
Data WAR / WAW	Anti- and output dependencies	Register renaming	Only in out-of-order designs
Control	Branch outcome unknown at fetch	Prediction + speculative execution	Misprediction penalty × rate
Memory ordering	Loads and stores to the same address	Store buffer with forwarding, memory disambiguation	Complexity

Table 58. Branch prediction

Predictor	Mechanism	Typical accuracy
Static (backward taken)	Loop heuristic	~65%
Bimodal	2-bit saturating counter per PC	~85%
gshare	Global history XOR PC indexes the table	~93%
Tournament	Choose between local and global predictors	~95%
TAGE	Multiple history lengths with tags	>97%
Perceptron	Linear classifier over history	>97%
Return address stack	Dedicated stack for call/return	>99% for returns

Graduate · Why a misprediction is expensive and getting more so. The penalty is the pipeline depth from fetch to resolve. In a 5-stage machine that is 2–3 cycles; in a 15-stage out-of-order machine it is 15–20, and the machine may have to discard dozens of in-flight instructions. With a 5% miss rate and a 15-cycle penalty, branches alone cost 0.75 cycles per branch — often more than every other stall combined. This is why predictor research continues to be worthwhile and why deep pipelines

have diminishing returns. **For an accelerator IP designer the lesson is the opposite and liberating: a fixed-function datapath has no branches, so none of this cost exists.** Quantifying that difference — "your software loop spends 0.75 cycles per iteration on branch misprediction alone" — is one of the strongest arguments an accelerator vendor has.

D2.2 Out-of-order execution

Table 59. Out-of-order machinery

Structure	Purpose	Scaling limit
Register renaming (RAT)	Removes WAR/WAW	Physical register file size
Reservation stations / issue queue	Hold instructions until operands ready	Wakeup-select loop is the critical path
Reorder buffer (ROB)	In-order commit → precise exceptions	Entries scale with memory latency
Load/store queue	Memory disambiguation	Associative search cost
Scoreboard	Simpler alternative (no renaming)	Stalls on WAR/WAW

Graduate · The **wakeup-select loop** — broadcasting a result tag, waking dependent instructions, selecting which to issue — must complete in one cycle for back-to-back dependent execution. It is a broadcast across the whole issue queue, so its delay grows with queue size and with issue width. This single loop, not transistor speed, is why issue widths have plateaued around 4–8 and why further performance has come from more cores rather than wider ones. **It is the same phenomenon as the DFE feedback loop and the Viterbi ACS loop: a recurrence whose latency cannot be pipelined away.** Recognising the pattern across domains is exactly the transferable skill this book aims to build.

D3. Memory Hierarchy and Coherence

Each level is roughly an order of magnitude slower and larger

Figure 8. The memory hierarchy. Each level trades capacity against latency by roughly an order of magnitude.

Table 60. Cache design parameters

Parameter	Effect	Trade
Block size	Exploits spatial locality	Too large wastes bandwidth and causes false sharing
Associativity	Reduces conflict misses	More comparators, longer hit time; 4–8 way is the usual optimum
Capacity	Reduces capacity misses	Area, leakage, hit latency
Write policy	Write-through vs write-back	Write-back reduces bandwidth; needs dirty bits and coherence
Allocation	Write-allocate vs not	Depends on write locality
Replacement	LRU / pseudo-LRU / random	True LRU is expensive beyond 4-way; pseudo-LRU is within 1%
Inclusion	Inclusive / exclusive / NINE	Affects snoop filtering

Undergraduate review · Misses classify as **compulsory** (first reference), **capacity** (working set exceeds the cache), **conflict** (limited associativity), and in multiprocessors **coherence** (invalidated by another core). The classification is useful because each class has a different remedy: prefetching for compulsory, larger cache for capacity, higher associativity or better indexing for conflict, and data layout changes for coherence.

Table 61. Coherence protocols

Protocol	States	Note
MSI	Modified, Shared, Invalid	Minimal
MESI	+ Exclusive	Avoids a bus transaction on read–modify
MOESI	+ Owned	Allows dirty sharing; saves writebacks
Directory-based	—	Scales beyond a bus ; required for many-core
Snoop filter	—	Reduces useless snoops in large systems

Graduate · Memory consistency is not coherence. Coherence concerns a single address — all cores must see one order of writes to it. Consistency concerns the relative order of operations to *different* addresses. A machine can be perfectly coherent and still reorder a store to A before a store to B as observed by another core. The consistency model (sequential, TSO, release, RVWMO) specifies what reorderings are allowed and which fences prevent them. **For a modelling engineer this is the hardest specification to capture**, because the reference model is inherently sequential while the hardware is not: a simple step-and-compare against an ISS *cannot* verify a weak memory model. The correct approach is **litmus tests** — short multi-threaded programs with enumerated permitted outcomes — checked against the architecture's formal memory model. Knowing that a different verification technique is required, and why, is the point.

Table 62. DRAM characteristics that leak into system design

Property	Meaning	Design response
Row buffer	A row must be activated before access	Exploit row locality; schedule for open rows
$t_{\text{RCD}}, t_{\text{RP}}, t_{\text{RAS}}$	Activate/precharge timings	Memory controller scheduling
Refresh	Every ~32–64 ms	Blocks access; matters for real-time guarantees
Bank/rank parallelism	Independent banks	Interleave addresses to exploit it
Burst length	Minimum transfer granularity	A 4-byte read still fetches 32–64 bytes
Rowhammer	Repeated activation disturbs neighbours	A security problem solved by refresh management — a DRAM controller feature

E1. Digital Filters as Hardware

Direct form: adder tree depth grows with N

Transposed form: critical path is one mult + one add, independent of N

Figure 9. Direct-form FIR. The tap count sets the multiplier count; the *form* sets the critical path.

Table 63. FIR structures and their costs

Structure	Multipliers	Critical path	Choose when
Direct form	N	1 mult + $\log N$ adds	N small
Transposed direct form	N	1 mult + 1 add (constant)	Almost always, for speed. Cost: high fanout on $x[n]$
Symmetric (folded)	$\lceil N/2 \rceil$	1 add + 1 mult + 1 add	Linear phase — free 2× saving
Polyphase	N/M effective	—	Combined with rate change
Distributed arithmetic	0 (LUTs)	W cycles	Fixed coefficients, LUT fabric
CSD / multiplierless	0	adds only	Fixed coefficients, ASIC area
Frequency domain	—	—	$N \gtrsim 100$ and block latency acceptable

Graduate · The fanout cost of the transposed form is real and is often overlooked in architecture documents. The input sample must reach all N multipliers in one cycle. For $N = 128$ at 500 MHz this is a significant buffer tree whose delay and power must be budgeted. The usual remedy is to *partition* the filter into segments with a pipelined input distribution network — effectively reintroducing a small amount of direct-form structure. **Real designs are hybrids, and a specification that names only "transposed FIR" is incomplete.**

E1.2 Filter design methods

Table 64. FIR design methods

Method	Optimality	Control	Use
Windowing	Suboptimal	Simple	Quick designs
Frequency sampling	Suboptimal	Direct in frequency	—
Parks–McClellan (Remez)	Minimax optimal	Ripple in each band	Standard for equiripple specs
Least squares	L2 optimal	Weighted error	When energy matters more than peak
Convex optimisation	Flexible	Arbitrary constraints	Handles quantised coefficients directly

Graduate · Designing in floating point and rounding afterwards is a mistake that costs stopband attenuation. Rounding a Parks–McClellan design to B bits perturbs each coefficient by up to half an LSB, and the resulting stopband degradation can be 10–20 dB. The correct procedure is to include the quantisation in the design: either use an integer-programming or convex formulation that searches over representable coefficients, or re-optimize the remaining coefficients after fixing some. **For an IP vendor this is a concrete deliverable: ship the coefficient generator, not just the coefficients**, so the customer can re-tune for their own band plan without repeating the analysis.

E1.3 Multirate structures

Table 65. Rate conversion building blocks

Block	Function	Key property
Decimator ($\downarrow M$)	Filter then discard $M-1$ of every M	Filter first , or aliasing is irreversible
Interpolator ($\uparrow L$)	Insert $L-1$ zeros then filter	Zeros create images; the filter removes them
Polyphase decomposition	Split the filter into M sub-filters	Avoids computing samples that are discarded — $M\times$ saving
CIC	Integrator–comb cascade	No multipliers ; passband droop must be compensated
Half-band	Every other coefficient is zero	$\sim 2\times$ saving for 2:1 rates
Farrow	Polynomial interpolation with variable delay	Arbitrary, time-varying resampling ratio — used in timing recovery

Graduate · The CIC word-growth question is a classic fixed-point trap. An N -stage CIC with rate change R and differential delay M has DC gain $(RM)^N$, so the integrators need $W_{\text{out}} = W_{\text{in}} + N \log_2(RM)$ bits. The textbook trick is to use **two's-complement wrap-around** in the integrators: intermediate values overflow, but because the comb stages later subtract, the overflow cancels exactly, provided the *final* result fits. This works because wrap-around arithmetic is a ring homomorphism. **Replace wrap with saturation — an apparently safer choice — and the cancellation is destroyed and the filter breaks.** A specification that says only "use saturating arithmetic throughout" would silently kill a correct CIC. This is why Part A's number-system chapter insists that overflow behaviour is a per-block decision.

E1.4 Adaptive filters

Table 66. Adaptive algorithms in hardware terms

Algorithm	Update	Multipliers per tap per update	Convergence
LMS	$\mathbf{w} \leftarrow \mathbf{w} + \mu \mathbf{e} \mathbf{x}^*$	2	Slow; sensitive to eigenvalue spread
NLMS	μ normalised by $\ \mathbf{x}\ ^2$	2 + norm	Robust to input level
Sign-error LMS	uses $\text{sgn}(\mathbf{e})$	1	Slower

Algorithm	Update	Multipliers per tap per update	Convergence
Sign-data LMS	uses $\text{sgn}(x)$	1	Slower
Sign-sign LMS	both signs	0 — adds only	Slowest; used in every high-speed SerDes
RLS	inverse correlation update	$O(N)$ per tap	Fast; expensive
Frequency-domain LMS	block FFT	—	Fast for long filters

Graduate · Why sign-sign LMS dominates at 56 GBd. Two independent facts combine. First, the channel changes on a timescale of milliseconds while symbols arrive every 18 ps — **adaptation can be nine orders of magnitude slower than the datapath**. Second, multipliers cannot run at the symbol rate at all. Taking only signs reduces the update to increment/decrement, which can be accumulated over thousands of symbols and applied occasionally. The resulting architecture has a *fast datapath* and a *slow adaptation loop* in a different clock domain. **For a modelling engineer this separation must be explicit in the model**, because a model that updates taps every symbol will not match RTL that updates them every 4096 symbols, even though both "implement sign-sign LMS". The update schedule is part of the specification.

E2. Transforms in Hardware: FFT and Friends

Table 67. FFT algorithm families

Algorithm	Complex multiplies	Structure	Note
Radix-2 DIT/DIF	$(N/2)\log_2 N$	Regular butterflies	Simplest control
Radix-4	fewer	4-point butterflies	~25% fewer multiplies
Split-radix	fewest for radix-2 ^k	Irregular	Control complexity
Winograd / PFA	Minimum multiplies	Length must factor into coprimes	Niche
Pipelined SDF	—	One butterfly per stage + delay line	Streaming; the standard for OFDM
MDC	—	Multiple data paths	Higher throughput
SSR / parallel	—	Several samples per clock	When the data rate exceeds the clock rate

Graduate · The resource that actually limits an FFT is memory and the twiddle factors, not the butterflies. A pipelined N -point SDF FFT needs $\log_2 N$ butterflies but a total of $N-1$ words of delay line, and a twiddle ROM whose size grows with N . For $N = 4096$ that is thousands of words of storage against a dozen arithmetic units. Two standard optimisations follow: exploit twiddle symmetry to store only one eighth of a period and derive the rest by sign and swap, or generate twiddles with a CORDIC instead of a ROM. **Which one wins depends on whether the target has cheap memory (FPGA) or cheap logic (ASIC)** — another instance of the rule that architecture choices are technology-dependent and must be re-derived, not memorised.

Bit-reversed output order is an interface decision, not an implementation detail. A DIF FFT naturally produces its output in bit-reversed order. Reordering costs a full N -word buffer and its bandwidth. In many systems the consumer — a channel equaliser, a magnitude detector — does not care about order, so the reordering is pure waste. Competent designs pass the bit-reversed order through and let the next block absorb it. **This means the reference model and the RTL will disagree about output order unless the specification says which convention is normative**, and a large fraction of "FFT mismatch" bug reports are exactly this.

Table 68. Numerical behaviour of fixed-point FFT

Issue	Cause	Handling
Magnitude growth	Each radix-2 stage can double magnitude	Scale by $\frac{1}{2}$ per stage (lose SNR), grow the word, or block floating point
Twiddle quantisation	Finite coefficient precision	Adds a noise floor; usually 2–4 bits more than data width
Rounding vs truncation	Bias accumulates over $\log N$ stages	Convergent rounding avoids DC bias
Overflow detection	Input-dependent	Saturate and flag, or scale conservatively

Table 69. Other transforms used in IP

Transform	Property	Application
DCT-II	Energy compaction for correlated signals	JPEG, H.264/HEVC (integer approximations)
Integer DCT	Exactly invertible, multiplier-free	Video codecs — avoids encoder/decoder drift
Hadamard	± 1 only	Secondary transform, spreading

Transform	Property	Application
Number-theoretic (NTT)	Exact modular arithmetic	Post-quantum crypto (ML-KEM/ML-DSA) , homomorphic encryption
Wavelet (DWT)	Time–frequency localisation	JPEG2000, denoising

Graduate · **The integer DCT in video codecs is a beautiful example of specification-driven design.** An exact DCT requires irrational coefficients; any two implementations would round differently, and since the decoder's output feeds back into the encoder's prediction loop, the tiny differences would accumulate into visible *drift*. H.264 solved this by **defining the transform to be a specific integer matrix**, so every conforming implementation produces bit-identical results. The lesson generalises directly to IP work: **when an algorithm sits in a feedback loop that spans two independently implemented systems, the specification must be bit-exact, not mathematical.** The same reasoning applies to a DFE's tap update, to an adaptive equaliser shared between link partners, and to any distributed control loop.

F1. The Wireline Link, End to End

Figure 10. A modern ADC-DSP receiver. The PMA/PCS boundary is also the boundary of what can be sold as soft IP.

F1.1 Why the architecture looks like this

The structure above is not arbitrary; each block exists because a specific physical limit made the previous approach fail. Following that chain is the fastest way to understand the field.

Table 70. The forcing chain

Limit encountered	Response	New problem created
Channel loss rises as $\sqrt{f}$ (skin effect)	Equalise	Analogue boost amplifies noise as well as signal
CTLE alone cannot open the eye at 30 dB loss	Add DFE (subtracts decided symbols, no noise gain)	DFE feedback must close within 1 UI
1 UI = 17.86 ps at 56 GBd; latch + summer + wire + setup > 23 ps	Speculate (unroll) and parallelise (sub-rate)	Area grows; still not enough alone
Baud rate cannot be raised further — the channel will not pass it	PAM4 : two bits per symbol at the same baud rate	9.54 dB SNR penalty
PAM4 raw BER is $\sim 10^{-4}$, far from 10^{-15}	Forward error correction (RS-FEC KP4)	Latency, and FEC becomes mandatory in the standard
Analogue equalisation cannot be adapted precisely enough	Sample first with a fast ADC, equalise digitally	Time-interleaved ADC mismatch; huge digital block
200 Gb/s per lane: even KP4 is not enough	Concatenated FEC (outer RS-KP4 + inner Hamming)	More latency; more complex decoder

Graduate · This table is the single most useful thing to memorise about high-speed links, because it lets you derive the architecture rather than recall it, and it identifies where a newcomer can contribute. Notice that the last four rows are all *digital* responses to *analogue* limits. That migration — from analogue equalisation to digital — is why a digital IP house can participate in SerDes at all, and it is still in progress.

F1.2 Timing budget arithmetic

Table 71. DFE first-tap loop budget at 56 GBd (1 UI = 17.86 ps)

Element	Delay	Comment
Slicer (latch) clock-to-Q	12 ps	Regeneration plus output drive
Summer	8 ps	Analogue summing node settling
Wiring	6 ps	Layout-dependent; often underestimated
Setup at next slicer	5 ps	—
Total loop	31.0 ps	—
Available	17.86 ps	1 UI
Margin	-13.14 ps	Infeasible
Latch + wire + setup alone	23 ps	Still exceeds 1 UI

The last row is decisive and is often missed. Unrolling removes the *summer* from the loop by pre-computing both hypotheses, but the latch, the wiring and the setup time remain — and they already exceed one UI. **Therefore no amount of speculation alone reaches 56 GBd; sub-rate parallelism is mandatory.** Stating this as a measured budget rather than an opinion is what turns an architecture argument into an engineering conclusion, and it is exactly the kind of analysis a modelling engineer is expected to produce before any RTL exists.

F1.3 Equaliser taxonomy

Table 72. Equalisers compared

Type	Location	Removes	Noise effect	Constraint
TX FFE (de-emphas-is)	Transmitter	Pre- and post-cursor	None (pre-distortion)	Reduces transmitted amplitude
CTLE	RX ana- logue	Broad high-frequency loss	Amplifies noise	Limited number of poles/zeros
RX FFE	RX digital	Pre- and post-cursor	Amplifies noise	Needs ADC; tap count $\times$ rate
DFE	RX digital	Post-cursor only	None (uses de- cisions)	1 UI loop; error propagation
MLSE / Viterbi	RX digital	Optimal sequence detec- tion	None	Complexity grows as M^L
Nonlinear (Volterra, NN)	RX digital	Nonlinear channel ef- fects	—	Training, complexity; an active research area

Graduate · Error propagation is the price of the DFE's noise-free subtraction. A wrong decision is fed back and corrupts the next few symbols, so errors arrive in bursts rather than independently. Two consequences follow, and both are design decisions rather than analysis details. First, the raw BER is worse than an independent-error model predicts, so a link budget built on Q-function arithmetic alone is optimistic. Second — and more usefully — **bursty errors are exactly what a symbol-oriented code like Reed–Solomon handles well**, because several wrong bits inside one symbol still count as one symbol error. The choice of RS over a binary code at the FEC layer is therefore partly a consequence of the DFE at the equaliser layer. **Layers that look independent in a block diagram are coupled through their error statistics.**

F1.4 Clock and data recovery

Table 73. CDR phase detectors

Detector	Samples needed	Characteristic	Used with
Alexander (bang-bang)	Data + edge (2×)	Binary output; nonlinear	Classic NRZ links
Hogge	Data + edge	Linear output	Lower jitter, more complex
Gardner	2× oversampling	Modulation-independent	Wireless, some wireline
Mueller–Müller	Baud-rate only	Uses ISI structure; needs equalised signal	ADC-DSP receivers — no 2× sampling needed
Oversampling / majority	3–8×	Simple, robust, low rate	Low-speed links, FPGA

Graduate · Why Mueller–Müller won in ADC-based receivers. At 56 GBd, sampling at 2× the baud rate means 112 GS/s — roughly doubling the ADC's power and area, which are already the dominant cost. MM extracts a timing error from baud-rate samples alone by exploiting the asymmetry of the equalised pulse response: it drives the sampling phase to the point where the first pre-cursor and first post-cursor are equal. The subtlety is that **MM's lock point depends on the equaliser**, so CDR and equaliser adaptation interact; a modelling engineer who simulates them independently will not see the interaction, and joint convergence failures are a classic late-stage surprise. **Model the loops together or state explicitly that you have not.**

F2. Error Control Coding

F2.1 The coding landscape

Table 74. Codes by structure and application

Family	Alphabet	Decoding	Strength	Typical use
Parity / SECDED	binary	syndrome	1-bit correct, 2-bit detect	Memory ECC , register files
Hamming / extended	binary	syndrome	—	Inner code in concatenation
BCH	binary	BM + Chien	t bit errors	Flash, optical
Reed–Solomon	$GF(2^m)$	syndrome $\rightarrow$ BM $\rightarrow$ Chien $\rightarrow$ Forney	t symbol errors — burst tolerant	Ethernet KP4 , storage, DVB
Convolutional	binary	Viterbi (ML)	Random errors	Legacy wireless, satellite
Turbo	binary	iterative BCJR	Near capacity	3G/4G
LDPC	binary	belief propagation (min-sum)	Near capacity	5G NR data , Wi-Fi, 802.3ca, NAND
Polar	binary	SC / SC-List	Provably capacity-achieving	5G control
Fountain (LT, Raptor)	binary	BP	Rateless	Broadcast, storage
Concatenated	mixed	inner then outer	Burst + random	802.3dj 224G , deep space

Graduate · **Choosing a code is choosing an error model.** A binary code assumes errors are independent bit flips; a symbol code assumes they cluster. Getting this wrong is expensive in both directions — a strong binary code performs poorly on bursts, and an RS code wastes redundancy on isolated bit errors. The correct procedure is to **measure the error statistics of the actual slicer output**, including DFE error propagation and any burst noise, and choose accordingly. In concatenated schemes the division of labour is explicit: the inner code cleans up random errors and the outer code mops up the bursts that the inner decoder's own failures produce. **The inner decoder's failure mode is the outer decoder's input distribution** — a subtlety that must be in the system model.

F2.2 Reed–Solomon in detail

Table 75. RS decoder pipeline

Stage	Computation	Parallelism	Hardware character
Syndrome	$S_i = r(\alpha^{tcr+i}), i=0\dots 2t-1$	Fully parallel ($2t$ independent evaluations)	$2t$ constant-multiplier accumulators
Key equation (BM)	Find $\sigma(x)$	Sequential — $2t$ dependent iterations	This is the critical path
Chien search	Roots of $\sigma(x)$	Parallel over positions	n/P cycles
Forney	$e_j = \omega/\sigma'$ evaluated at roots	Parallel	Needs GF inversion (ROM or Itoh–Tsujii)
Correction	XOR into the buffer	Parallel	Requires the codeword buffered

Graduate · The Berlekamp–Massey iteration is the same kind of obstacle as the DFE loop and the OOO wakeup loop. Each iteration depends on the previous discrepancy, so it cannot be pipelined away. The standard remedies mirror those in the other two cases: *inversionless* BM removes the GF inversion from the loop (replacing it with an extra multiplication), and *re-formulated* BM restructures the recurrence so that fewer operations sit inside it. A design house that recognises this pattern can move an engineer from a SerDes project to an FEC project and expect them to be productive quickly, because the underlying problem is identical.

Table 76. RS decoder behaviour that must appear in the datasheet

Condition	Behaviour	Why it must be documented
$\leq t$ symbol errors	Always corrected	The guarantee being sold
$> t$ errors	Detected or mis-corrected	Not all are detected. Claiming otherwise is false
Mis-correction probability	Roughly $n^t / (t! 2^{m(n-k-t)})$	Customers at 10^{-15} FLR need this number
Erasure decoding	Corrects up to $n-k$ erasures	If the receiver can flag unreliable symbols, capacity doubles
Latency	Fixed, = pipeline depth	Real-time systems need the number

“All errors beyond t are detected” is a false statement that appears in datasheets. A received word with more than t errors may land within distance t of a *different* valid codeword, in which case the decoder confidently produces the wrong answer. A measured illustration on a small code, RS(15,9) with $t = 3$: injecting exactly four symbol errors 120 times gave **117 detected failures and 3 mis-corrections** — never a correct recovery, but not always a detection either. An honest specification states the mis-correction probability; a verification plan must distinguish the three outcomes (corrected / detected / mis-corrected) rather than counting pass and fail.

F2.3 LDPC

Table 77. LDPC decoding choices

Choice	Options	Effect
Message form	Probability vs log-likelihood ratio	LLR turns products into sums — essential in hardware
Check-node update	Sum-product (tanh) vs min-sum	Min-sum loses ~ 0.5 dB, removes transcendental functions
Correction	Normalised or offset min-sum	Recovers most of the loss for one constant
Schedule	Flooding vs layered	Layered halves the iteration count; creates pipeline hazards
Parallelism	Fully parallel / row / block	Quasi-cyclic structure enables block parallelism
Early termination	Syndrome check per iteration	Large average power saving ; worst-case latency unchanged

LDPC's fixed-point rule is the opposite of the CIC's. An LLR's sign carries the hard decision. If an LLR wraps in two's complement, a strong belief in “0” becomes a strong belief in “1”, and the decoder does not merely lose precision — it is actively misled, and iteration amplifies the damage. Measured on a 5G NR base-graph decoder, reducing the message width by three bits gave BLER 0.250 with saturation and **1.000 — complete failure — with wrap-around**. Meanwhile the CIC filter of Chapter E1 *requires* wrap-around to function. **There is no global “correct” overflow policy; it is a per-block property that must be stated in the specification and enforced by tests.**

Graduate · **Layered scheduling and pipeline hazards.** In a layered decoder, layer j may need a variable node that layer i is still updating, forcing a stall whose length depends on the pipeline depth D and on the layer ordering. It is tempting to optimise the ordering against a closed-form stall count, but that formula is only an **upper bound**: it assumes every potential conflict costs a full stall. A measured comparison on 5G NR base graph 1 at $D = 4$ gave the formula 108 stall cycles while a cycle-accurate model and the RTL both gave **80** — the difference between a 70.1% and a 62.0% efficiency loss. **Optimising**

a schedule against the wrong objective function finds the wrong schedule. Build the cycle-accurate model first; it is a day of work and it changes the answer.

G1. Electromagnetics for the Digital Engineer

A digital IP engineer meets electromagnetics at three boundaries: the package and board that carry the block's signals, the channel a SerDes must equalise, and the antenna of a radio or radar system whose baseband processing is the block itself. This chapter covers what is needed at those boundaries.

G1.1 From Maxwell to circuits

Table 78. Regimes and the model that applies

Regime	Condition	Model	Consequence
Lumped	size $\ll \lambda$	KCL/KVL, R L C	Voltage is well defined everywhere
Quasi-static	size $\leq \lambda/10$	Lumped + parasitics	Inductance begins to matter
Distributed	size $\geq \lambda/10$	Transmission line	Position matters; reflections occur
Full wave	structure comparable to λ	Maxwell solvers	Radiation, resonance, modes

Graduate · **The threshold keeps moving toward the designer.** The criterion is not clock frequency but edge rate: significant spectral content extends to roughly $0.35/t_r$. A 50 ps edge has content to 7 GHz regardless of whether the clock is 100 MHz, and at 7 GHz a 2 cm trace is a transmission line. **Slow clocks do not protect you from fast edges.** This is why deliberately slowing output slew rates is a legitimate design technique — and why an IP's output driver strength is a specification item with EMI consequences, not just a timing one.

G1.2 Transmission lines

$$Z_0 = \sqrt{(R + j\omega L)/(G + j\omega C)} \rightarrow \sqrt{L/C} \text{ (lossless)}$$

Table 79. Line types

Type	Z_0 range	Where
Microstrip	50–100 Ω	Outer PCB layer; radiates more
Stripline	50–100 Ω	Inner layer; better shielded, slower (higher ϵ_{eff})
Coplanar waveguide	tunable	On-chip RF; ground on the same layer
Differential pair	85–100 Ω differential	The standard for high-speed serial
On-chip global wire	—	Usually RC-dominated, not a true TL

Table 80. Termination strategies

Scheme	Placement	Power	Note
Series (source)	At driver	Low	Doubles the driver's output swing requirement
Parallel	At receiver	High (static)	Best match
Thevenin	At receiver	High	Sets a DC bias
AC-coupled	In line	Low	Requires DC-balanced coding (8b/10b, 64b/66b)
On-die termination (ODT)	Inside the chip	Moderate	Calibrated against an external precision resistor

Graduate · **AC coupling and line coding are linked requirements.** A series capacitor blocks DC, so a long run of identical symbols causes the signal to droop toward the decision threshold — baseline wander. The line code must therefore bound the run length and keep the running disparity small. 8b/10b does this with an explicit disparity rule at 25% overhead; 64b/66b uses a scrambler and accepts a small probability of a long run, at 3% overhead. **The coding choice is thus determined by an analogue component.** An engineer who knows only the coding layer cannot explain why 64b/66b needs a scrambler with a particular polynomial, nor why certain data patterns are used as stress tests.

G1.3 Antennas and propagation

$$P_r = P_t G_t G_r (\lambda/4\pi d)^2 \quad (\text{Friis})$$

Table 81. Antenna and propagation quantities

Quantity	Definition	Design relevance
Gain G	Directivity × efficiency	Trades coverage for range
Effective aperture	$A_e = G\lambda^2/4\pi$	Higher frequency → smaller aperture for the same gain
Beamwidth	$\approx 70^\circ/\sqrt{D}$	Array size sets angular resolution
Path loss exponent	2 (free space) to 4+ (urban)	Link budget
Multipath / delay spread	—	Sets the equaliser or OFDM CP length
Doppler shift	$f_d = 2v/\lambda$	Coherence time; tracking loop bandwidth
Fading	Rayleigh / Rician	Diversity, MIMO

Graduate · **Delay spread converts directly into a hardware parameter.** If the channel's impulse response lasts $\tau_{\max}$, a single-carrier receiver needs an equaliser spanning $\tau_{\max}/T_s$ symbols, and an OFDM receiver needs a cyclic prefix at least that long. The first costs taps (area, adaptation time); the second costs throughput (the CP is overhead). **This is the quantitative form of the choice between single-carrier and OFDM**, and it explains why wireline links — where delay spread is long but the channel is static — use equalisers, while wireless links with time-varying multipath use OFDM. The same physics, opposite conclusions, because the *rate of change* differs.

G1.4 Noise figure and receiver chains

$$F_{\text{total}} = F_1 + (F_2 - 1)/G_1 + (F_3 - 1)/(G_1 G_2) + \dots$$

Graduate · **Friis's formula justifies the entire architecture of a receiver front end.** Because later stages are divided by the cumulative gain ahead of them, the first amplifier dominates the noise figure — hence the low-noise amplifier, placed as close to the antenna as possible, often before any filter whose insertion loss would add directly to F_1 . The counterweight is linearity: gain early in the chain means large signals later, so the cascaded third-order intercept point degrades as $1/\text{IIP3}_{\text{total}} = 1/\text{IIP3}_1 + G_1/\text{IIP3}_2 + \dots$ **Noise pushes gain forward; linearity pushes it backward.** Every receiver's gain distribution is a solution to that tension, and the digital back end inherits the result as its required dynamic range — which is to say, as its ADC bit count.

G2. Radar: Signal Processing as an IP Block Family

Automotive and industrial radar is one of the largest current markets for signal-processing IP, and its chain is a clean illustration of how physical parameters become hardware parameters.

$$P_r = P_t G^2 \lambda^2 \sigma / ((4\pi)^3 R^4) \quad (\text{radar equation})$$

Undergraduate review · The fourth-power range dependence is the defining fact of radar: doubling the detection range requires sixteen times the received power. Since transmit power and antenna gain are bounded, the remaining lever is **processing gain** — coherent integration — which is entirely a digital matter and therefore entirely IP.

$$\text{Beat frequency } f_b = 2 \cdot R \cdot S / c \quad (S = \text{chirp slope})$$

Range from frequency; velocity from phase change across chirps

Figure 11. FMCW radar. Range appears as a beat frequency; velocity appears as phase progression across successive chirps.

G2.1 FMCW parameter derivation

Table 82. From requirement to hardware parameter

Requirement	Relation	Hardware consequence
Range resolution ΔR	$\Delta R = c/2B$	Sweep bandwidth — 4 GHz gives 3.75 cm
Maximum range $R_{\max}$	$f_{b,\max} = 2R_{\max}S/c$	ADC sample rate and IF bandwidth
Velocity resolution Δv	$\Delta v = \lambda/(2N_c T_c)$	Number of chirps per frame → frame memory
Maximum velocity	$v_{\max} = \lambda/(4T_c)$	Chirp repetition period
Angular resolution	$\approx \lambda/(N_a d \cos\theta)$	Number of antennas → number of RX chains
Processing gain	$10\log(N_s N_c)$	FFT sizes → compute and memory

Graduate · **The range–Doppler map is a two-dimensional FFT** and its dimensions come straight from the table: a fast-time FFT across samples within one chirp yields range bins; a slow-time FFT across chirps at each range bin yields Doppler bins. A typical automotive frame — 256 samples $\times$ 128 chirps $\times$ 8 virtual antennas — requires a corner-turn between the two FFTs, and **that transpose, not the FFTs, dominates the memory bandwidth**. Designing the memory organisation (ping-pong banks, tiled transpose, or on-the-fly second-stage accumulation) is the real architectural work. This is a recurring theme: in data-intensive blocks the arithmetic is rarely the bottleneck.

G2.2 Detection

Table 83. CFAR detectors

Type	Noise estimate	Strength	Weakness
CA-CFAR	Mean of surrounding cells	Simple, efficient in homogeneous noise	Masks targets near clutter edges
GO-CFAR	Greater of the two halves	Handles clutter edges	Loses closely spaced targets
SO-CFAR	Smaller of the two halves	Resolves close targets	High false alarm at edges
OS-CFAR	k -th order statistic	Robust to interfering targets	Needs a sorter — more hardware
Adaptive / ML	learned	Best in complex scenes	Verification difficulty

Graduate · **CFAR sets a threshold, not a decision**. The multiplier α is chosen so that the probability of false alarm is fixed regardless of the noise level — that is what "constant false alarm rate" means. For CA-CFAR with N reference cells, $\alpha = N(P_{FA}^{-1/N} - 1)$. Two hardware consequences: the block needs a divider or a reciprocal table, and it needs the N reference cells buffered, which for a 2-D CFAR means a sliding window over a two-dimensional array. **OS-CFAR's sorter is the most hardware-hungry element in a typical radar back end**, and choosing between a full sorting network and an approximate selection is a genuine PPA decision that a design house can differentiate on.

G2.3 Angle estimation and MIMO

Table 84. Angle-of-arrival methods

Method	Resolution	Computation	Robustness
FFT beamforming	Rayleigh limit	One FFT	Very robust
Capon / MVDR	Super-resolution	Matrix inverse per snapshot	Needs good covariance estimate
MUSIC	Super-resolution	Eigendecomposition	Needs the source count
ESPRIT	Super-resolution	SVD + rotation	Needs array structure
Compressive sensing	High	Iterative solver	Sensitive to model mismatch

Graduate · **This is where Part A's matrix decompositions become products**. MUSIC needs the eigendecomposition of an $N \times N$ covariance matrix per snapshot; Capon needs its inverse. For an 8–16 element array that is a small, dense, Hermitian, **positive-definite** problem — exactly the case where Cholesky applies and streams. A design house that owns a parameterised streaming Cholesky or Jacobi eigenvalue block can sell it into radar, into MIMO communications, and into adaptive beamforming, because all three reduce to the same kernel. **Recognising that one kernel serves three markets is how a small IP portfolio becomes viable**.

Graduate · **MIMO radar's virtual array** deserves a precise statement because it is the main reason automotive radar improved so quickly. With N_t transmitters and N_r receivers, transmitting orthogonal waveforms (time-, frequency-, or code-division) and separating them at the receiver yields $N_t \times N_r$ distinct transmit–receive paths, which behave like a physical array of

that many elements. Three transmitters and four receivers give a twelve-element virtual array — a threefold improvement in angular resolution at the cost of **digital** separation logic rather than antennas and RF chains. **Once again the solution to a physical limit is a digital block.**

H1. Verification: Theory and Organisation

Figure 12. The three-team structure. It exists to make “correct” an operational, testable notion.

Verification consumes more effort than design in every serious IP project — commonly cited at 60–70% of the schedule. Understanding why it is organised as it is prevents a great deal of wasted work.

H1.1 Why two independent implementations

Undergraduate review · A specification written in prose is ambiguous; a single implementation is self-consistent by construction and therefore cannot reveal its own misreadings. Two implementations built independently from the same specification will agree only where both read it the same way. **Disagreement localises ambiguity.** This is the same principle as dissimilar redundancy in avionics, applied to development rather than to operation.

Graduate · **The argument fails if the two implementations are not independent.** If the modeller and the designer sit together, share an interpretation, and one consults the other's code when unsure, the common-mode error rate rises and the regression turns green on a shared misunderstanding. Organisations counter this in three ways: physical or organisational separation; deriving one implementation from a **formal, executable specification** (the RISC-V Sail model is the canonical example, generating both prose and a C emulator from one source); and an **external oracle** — standard test vectors from NIST, IEEE or a conformance suite. **The third is the strongest and the cheapest, and it is the reason standards-based blocks are the best first product for a small IP house.**

H1.2 The verification stack

Table 85. Verification levels

Level	Checks	Catches	Cannot catch
Lint	Coding rules	Latches, width mismatches, incomplete sensitivity	Anything functional
CDC / RDC static	Crossing structure	Missing synchronisers, reconvergence	Functional protocol errors
Unit simulation	Block behaviour vs model	Most functional bugs	Integration, timing
Formal property	Exhaustive over state space	Deadlock, unreachable states, protocol violations	Deep datapath equivalence (state explosion)
Formal equivalence (LEC)	RTL vs netlist	Synthesis and ECO errors	Specification errors
Integration / SoC sim	Blocks together	Interface mismatches, arbitration	Long-running system behaviour
Gate-level with timing	Netlist + SDF	X-propagation, timing-dependent bugs	Slow; limited coverage
Emulation / FPGA prototype	Real software on real RTL	Software-visible bugs, long sequences	Analogue, timing corners
Post-silicon	Actual device	Everything else	— but fixes are expensive

X-propagation deserves a specific warning because it is asymmetric between RTL and gates. In RTL simulation, an if (x) with an unknown condition may take a branch and produce a definite value, hiding the uncertainty — this is *X-optimism*. In gate-level simulation the same unknown spreads — *X-pessimism*. A design that relies on registers being initialised by data flow rather than by reset can therefore pass RTL simulation and fail in gates, or vice versa. The remedies are X-propagation-aware simulation modes and, better, **explicit initialisation of any register whose value is read before it is written**. For an IP vendor this is also a deliverable question: if your block requires *n* cycles of reset before its outputs are valid, say so.

H1.3 Coverage and closure

Table 86. Coverage metrics

Metric	Measures	Automat-ic?	Weakness
Line / block	Statements executed	Yes	Says nothing about values
Branch / condition	Decisions taken	Yes	—
Expression (MC/DC)	Each condition independently affects the outcome	Yes	Required for DO-254 / ISO 26262
Toggle	Every bit changed both ways	Yes	Weak functional signal
FSM state / transition	States and arcs visited	Yes	—
Functional (coverage groups)	Scenarios the engineer defined	No	Blind to scenarios nobody thought of
Assertion	Properties actually exercised	Partly	Vacuous passes must be excluded
Mutation / fault injection	Whether the testbench would notice a bug	Yes	The only metric that tests the testbench

Graduate · Mutation coverage is the metric that answers the question the others avoid: **would this testbench detect a bug if there were one?** The procedure is to inject a small, semantically meaningful change — invert a comparison, drop a term, stick a bit — and confirm the regression turns red. A mutant that survives identifies a check that does not exist or a stimulus that never reaches the code. This is cheap to automate and routinely reveals that a large fraction of a mature suite is

inert. **The same technique applies to the reference model itself**, which is otherwise unverified: break the model deliberately and confirm the model's own self-checks fail. A verified reference model is a differentiator that very few IP vendors can claim.

H1.4 The scoreboard problem

Table 87. Comparison strategies

Situation	Strategy	Pitfall
In-order, fixed latency	FIFO compare	—
In-order, variable latency	FIFO + timeout	Timeout too tight → false failures
Out-of-order, tagged	Per-tag queues	A single queue produces both false failures and false passes
Multiple legal orders	Compare against a set of allowed outcomes	Requires the model to enumerate them
Don't-care fields	Mask before comparing	Masking too much hides real bugs
Weak memory model	Litmus tests , not trace comparison	Trace comparison is simply invalid here

Graduate · The AXI case is worth stating concretely because it is so common. AXI guarantees ordering only *within* an ID; transactions with different IDs may complete in any order. A scoreboard with one queue will report a failure when the DUT legitimately reorders across IDs, and — more dangerously — may accept a genuine intra-ID reordering as long as the totals match. **The correct structure is one queue per ID**, and knowing this is a direct consequence of having read the protocol specification rather than inferring behaviour from waveforms. It is a frequent and productive point of contact between the modelling and verification teams.

H1.5 Regression engineering

Table 88. Regression discipline

Practice	Reason
Record the seed with every run	Without it a failure is not reproducible
Classify failures automatically	Triage time dominates otherwise
Track failure <i>signatures</i> , not counts	Distinguishes new from known
Never close an intermittent failure as 'flaky'	Intermittent failures are usually real races
Keep a golden log of the last known-good	Enables bisection
Measure regression runtime	A suite nobody can run nightly is not a suite
Separate infrastructure failures	Licence and disk errors must not be counted as bugs

The prohibition on dismissing intermittent failures is the most frequently violated rule in this book. An intermittent failure means the outcome depends on something the test does not control — a race, an uninitialised value, a timing-dependent path. All three exist in the silicon too. **Closing such a ticket does not remove the bug; it removes the evidence.** The correct disposition is to keep it open with the failing seed recorded, even if it cannot be root-caused immediately.

H2. The Implementation Flow

Table 89. From RTL to GDSII

Step	Input → output	Key decisions	Common failure
Elaboration	RTL → generic netlist	Parameter resolution	Unintended latch inference
Logic synthesis	generic → standard cells	Constraints, effort, V_{TH} mix	Over-constrained clock → area and power explosion
DFT insertion	+ scan chains	Chain count and length	Scan shift timing
Floorplan	—	Block placement, pin assignment, power grid	The decision with the largest downstream impact
Placement	cells → locations	Congestion vs timing	Routing congestion
CTS	+ clock tree	Skew target, useful skew	Clock power, OCV
Routing	—	Layer assignment, shielding	DRC violations, crosstalk
Sign-off STA	—	Corners, derating, SI	Missing a corner
Physical verification	DRC, LVS, antenna	—	—
Extraction + final timing	RC → delays	—	—

Graduate · Floorplanning is where an IP block's shape becomes a commercial issue. A block delivered as RTL will be placed by the customer, whose aspect ratio, pin locations and macro placement may be nothing like the vendor's. If the block's internal timing depends on a particular arrangement — a wide datapath that must stay compact, a memory that must sit next to its controller — then the RTL alone is not a sufficient deliverable. Serious IP therefore ships a **floorplan guideline**, sometimes a hardened macro, and always a statement of the assumed aspect ratio and utilisation. **A block that met timing in the vendor's flow and misses in the customer's is the single most damaging support event a small IP house can have**, because it is expensive to debug remotely and it destroys confidence.

Table 90. Sign-off corners

Axis	Values	Why
Process	SS, TT, FF, SF, FS	Global and local variation
Voltage	min, nominal, max	IR drop and regulation tolerance
Temperature	−40, 25, 125 °C	Both extremes — temperature inversion makes cold the worst case at low V
RC extraction	Cmin, Cmax, RCmin, RCmax	Metal thickness variation
Mode	functional, scan, BIST, low power	Different constraints apply
Ageing	fresh, end-of-life	NBTI/PBTI drift

Graduate · The corner count multiplies. Five process points × three voltages × three temperatures × four RC × four modes is 720 combinations; full sign-off on all of them is not affordable. The industry response is **statistical or parametric OCV** (POCV), which models variation as a distribution rather than enumerating corners, plus careful selection of dominant corners. For an IP vendor the practical obligation is to state **which corners were signed off** in the PPA report. "500 MHz" without a corner is not a specification, and a customer who assumes typical-typical will be disappointed at slow-slow.

Table 91. High-level synthesis in the flow

Aspect	Reality
Input	C/C++/SystemC with vendor pragmas — not portable across tools
Strength	Design-space exploration: one source, many area/throughput points
Weakness	Generated RTL is hard to read and debug; timing closure less predictable
Where it wins	Datapath-dominated blocks with regular loops (filters, transforms, crypto)
Where it loses	Control-dominated logic, precise cycle-level interfaces
Verification role	The same C source doubles as the reference model , because a general compiler ignores the pragmas — convenient, but it shares every algorithmic assumption with the design

The last row is a genuine methodological trap. Using the HLS source as the golden model gives *zero* independence: the two implementations are literally the same text. It verifies the HLS tool, not the design. **If the HLS C is the design, the reference model must be written separately** — ideally in a different language, by a different person, from the specification.

H3. Hardware Security

Table 92. Threat model, mechanism, countermeasure

Threat	Mechanism	Countermeasure	Verifiable by simulation?
Timing side channel	Execution time depends on secret	Constant-time algorithms; no secret-dependent branches or table indices	Partly — can check control flow
Power / EM (SPA, DPA, CPA)	Switching activity correlates with data	Masking (Boolean or arithmetic), threshold implementations, DOM	No — requires TVLA on silicon or power simulation
Fault injection (laser, glitch, EM)	Flip a bit to skip a round or corrupt a check	Redundant/complementary FSMs, computation duplication, output checks	Partly — by explicit fault simulation
Probing / FIB	Physically read an internal wire	Shields, sensors, routing obfuscation	No
Scan / debug access	Read state through test infrastructure	Lock scan after test; life-cycle state control	Yes
Rowhammer memory disturb	Repeated activation flips neighbours	Refresh management, tracking	Partly
Supply chain	Trojan insertion, counterfeiting	Split manufacturing, logic locking, PUF identity	No

Graduate · The fourth column is the key organisational insight for a modelling engineer. A functional regression, no matter how complete, is blind to four of the seven rows. Saying “the AES block is verified” is therefore ambiguous, and in a security review the ambiguity will be challenged. The mature formulation is: *functional equivalence to FIPS-197 is verified by NIST vectors and constrained-random comparison against an independent model; side-channel resistance is assessed separately by TVLA on the test chip; fault resistance is assessed by gate-level fault injection. Three claims, three methods, three owners.*

Table 93. Masking: the principle and its cost

Concept	Statement	Consequence
Boolean masking	x represented as $(x \oplus m, m)$	Each share is independent of $x \rightarrow$ first-order leakage removed
Linear operations	Apply to each share separately	Nearly free
Nonlinear operations	Shares must interact	The expensive part — this is why the AES S-box is rebuilt in arithmetic
Glitches	Transient values can momentarily depend on x	Registers must separate share-combining stages
DOM	Domain separation + fresh randomness + registers	Provably glitch-resistant; needs a continuous randomness supply
Order d masking	$d+1$ shares resist d -th order analysis	Cost grows roughly as $(d+1)^2$

Graduate · Randomness becomes a system-level resource. A DOM-protected S-box consumes fresh random bits on every evaluation. An AES core performing sixteen S-box lookups per round for fourteen rounds therefore needs a sustained random-bit rate that a slow true-RNG cannot supply, so the design includes a fast PRNG reseeded from the TRNG. That PRNG's quality, its reseed policy, and its behaviour when starved are now **functional** requirements of the cipher block, and they are

verifiable. **A security countermeasure has turned into an ordinary functional specification with a throughput requirement** — which is precisely the kind of boundary a modelling engineer should be able to identify and take ownership of.

Table 94. Standards a security IP is measured against

Standard	Scope
FIPS 140-3	Cryptographic module validation
Common Criteria (ISO 15408)	Evaluation assurance levels
ISO/IEC 17825	Side-channel test methods
NIST CAVP	Algorithm test vectors — the practical oracle
SP 800-90A/B/C	RNG construction, entropy, and validation
FIPS 203/204/205	Post-quantum: ML-KEM, ML-DSA, SLH-DSA
OCP Caliptra	Datacentre root of trust specification
ISO 26262 / IEC 61508	Functional safety (distinct from security)

I1. Information Theory

I1.1 Entropy and its operational meanings

$$H(X) = -\sum_x p(x) \log_2 p(x) \quad I(X;Y) = H(X) - H(X|Y)$$

Table 95. Information-theoretic quantities and where they bind hardware

Quantity	Meaning	Operational limit it sets
Entropy $H(X)$	Average information per symbol	Lossless compression cannot go below it — bounds a co-dec's ratio
Min-entropy H_∞	$-\log_2 \max_x p(x)$	The measure NIST SP 800-90B requires for an entropy source; always $\leq H$
Conditional entropy	Remaining uncertainty given side information	Leakage analysis in side-channel evaluation
Mutual information	Information one variable carries about another	Side-channel leakage metric ; also the quantity maximised by capacity
Channel capacity C	$\max I(X;Y)$	No code can exceed it; tells you how far your FEC is from optimal
Rate-distortion $R(D)$	Minimum rate for distortion D	Lossy codec bound — the theoretical floor of a video encoder
Kolmogorov complexity	Shortest program producing the string	Uncomputable; conceptual only

Graduate · **Min-entropy is the one an IP engineer must get right, and it is not Shannon entropy.** A biased source that outputs 0 with probability 0.9 has Shannon entropy 0.47 bits but min-entropy only $-\log_2(0.9) = 0.152$ bits. Certification uses min-entropy because security must hold against the *most likely* guess, not the average case. A TRNG that claims "0.5 bits of entropy per sample" on Shannon grounds and is conditioned on that basis will fail validation and, worse, will produce keys with less unpredictability than advertised. **The conditioning ratio — how many raw bits are compressed into one output bit — is derived from min-entropy, and it is a hardware parameter.**

I1.2 Capacity results that matter in practice

Table 96. Capacity expressions

Channel	Capacity	Design meaning
AWGN	$B \log_2(1+\text{SNR})$	The reference against which every modem is measured
Binary symmetric (BSC)	$1 - H_b(p)$	Hard-decision decoding loses ~2 dB versus soft
Binary erasure (BEC)	$1 - \epsilon$	Erasure decoding doubles RS correction capability
MIMO ($N_t \times N_r$)	$\approx \min(N_t, N_r) \log(1+\text{SNR})$	Capacity scales with antennas, not power
Fading with CSI	$E[\log(1+ h ^2 \text{SNR})]$	Motivates adaptive modulation and coding
Band-limited with ISI	water-filling over the channel response	The theoretical justification for OFDM bit loading

Graduate · **The soft-versus-hard decision gap is the most actionable number here.** Passing hard decisions to a decoder discards the reliability information the slicer had, and costs roughly 2 dB on an AWGN channel. In a link budget 2 dB is enormous — it is the difference between needing an extra equaliser tap and not. This is why modern FEC interfaces carry

LLRs rather than bits, why the slicer in an ADC-based receiver reports a multi-bit soft value, and why the fixed-point width of that LLR is a system-level parameter rather than a local choice. **An interface that carries one bit where it could carry four has thrown away 2 dB before the decoder starts.**

I1.3 Source coding

Table 97. Compression methods in hardware

Method	Principle	Hardware character
Huffman	Prefix code by symbol probability	Table lookup; variable-length decode is serial
Canonical Huffman	Ordered code lengths	Compact tables, faster decode
Arithmetic / range	Interval subdivision	Better ratio; strictly serial — a throughput bottleneck
CABAC	Context-adaptive binary arithmetic	The critical path of an H.264/HEVC decoder
ANS / rANS	Asymmetric numeral systems	Arithmetic-coding ratio with table-driven speed; used in AV1, Zstd
LZ family	Dictionary matching	Match search is the expensive part
RLE	Run lengths	Trivial; still used for coefficient maps

Entropy coding is where video decoders stop parallelising. Transform, prediction and filtering all parallelise over blocks, but arithmetic decoding is inherently sequential: the next symbol's interval depends on the current state. This is why real decoders introduce architectural workarounds — slices and tiles that reset the context so they can be decoded independently, wavefront parallel processing, or the bypass modes that skip context modelling for near-uniform symbols. **The bitstream syntax was designed around a hardware constraint**, which is the clearest possible illustration that standards and architectures co-evolve.

I2. Algebraic Structures for Hardware

I2.1 Groups, rings, fields

Table 98. Structures and the hardware they license

Structure	Operations	Guarantee	Hardware consequence
Group	one associative op with inverses	Cancellation	Reversible transforms
Ring	+ and $\times$, no division	Closure under both	Two's-complement W-bit arithmetic is a ring — wrap-around is exact, so operation order does not matter
Field	+ $\times$ and division	Every non-zero element invertible	$GF(2^m)$ arithmetic for codes and crypto
Vector space over a field	—	Linearity	Linear codes: encoding and syndrome are matrix products
Polynomial ring $F[x]/(f)$	—	—	Cyclic codes, NTT, lattice cryptography

Graduate · The ring property of two's-complement arithmetic is the formal reason behind a practical rule. Because W -bit two's complement is the ring $\mathbb{Z}/2^W\mathbb{Z}$, addition and multiplication are exact modulo 2^W , associative and commutative. Intermediate overflow therefore cancels exactly, provided the final result is in range, and **the order of accumulation cannot change the answer**. Saturation destroys the ring structure: once a value is clamped, information is lost and order matters. This is why a CIC filter *requires* wrap-around and why an LDPC decoder *requires* saturation — the two blocks rely on opposite algebraic properties. **Stating this as algebra rather than as folklore makes it possible to decide the question for a new block instead of guessing.**

I2.2 Finite fields in detail

Table 99. $GF(2^m)$ implementation choices

Representation	Multiplication	Inversion	Best for
Polynomial basis	Shift-and-XOR, reduce	Extended Euclid or Itoh–Tsujii	General purpose; most codes
Normal basis	More complex	Squaring is a free cyclic shift	Inversion-heavy workloads (ECC)
Log/antilog tables	Add logs	Negate the log	Small fields ($m \leq 12$); the usual RS choice
Tower field	$GF(2^8) \rightarrow GF(2^4) \rightarrow GF(2^2)$	Recursive	Maskable — the AES DOM S-box
Composite field	—	—	Area reduction

Graduate · The choice of irreducible polynomial is a specification item, not an implementation detail. Two implementations of $GF(2^{10})$ using different primitive polynomials produce entirely different — though isomorphic — arithmetic, and codewords from one will not decode in the other. Standards therefore fix the polynomial: AES uses $x^8+x^4+x^3+x+1$, and IEEE 802.3 Clause 91 fixes the field for RS(544,514). **A reference model that hard-codes a plausible polynomial without checking the standard will interoperate with nothing.** The defensive practice is to make the polynomial a parameter, assert that it is primitive (verify that α generates all 2^m-1 non-zero elements), and record in the code whether the value has been confirmed against the specification text.

Table 100. Where finite fields appear

Application	Field	Operation that dominates
Reed–Solomon	$\text{GF}(2^8), \text{GF}(2^{10})$	Multiply, invert
BCH	$\text{GF}(2^m)$	Multiply
AES	$\text{GF}(2^8)$	Inverse (S-box), $\times 2$ and $\times 3$ (MixColumns)
AES-GCM	$\text{GF}(2^{128})$	Carry-less multiply
Elliptic curves	$\text{GF}(p)$ or $\text{GF}(2^m)$	Modular multiply (Montgomery)
ML-KEM / ML-DSA	$\mathbb{Z}_q[x]/(x^n+1)$	Number-theoretic transform
CRC	$\text{GF}(2)[x]$	Polynomial remainder (LFSR)
Erasure coding (RAID)	$\text{GF}(2^8)$	Matrix multiply

Graduate · Post-quantum cryptography brings a new arithmetic requirement into mainstream silicon. ML-KEM and ML-DSA operate in a polynomial ring modulo a small prime (3329 and 8380417 respectively), and their bottleneck is the number-theoretic transform — an FFT over that ring. The hardware looks like an FFT but with modular multipliers instead of complex ones, and modular reduction by a fixed small prime admits efficient tricks (Montgomery, Barrett, or prime-specific shift–add chains). **For a design house, an NTT block parameterised over modulus and length is a single kernel serving several standards**, in the same way that a Cholesky block serves radar, MIMO and beamforming. Finding these shared kernels is how a small portfolio covers a large market.

I3. Optimisation and Numerical Methods

Table 101. Optimisation problems that appear in IP design

Problem	Class	Method	Where
Filter coefficient design	Convex (minimax)	Remez, convex solvers	FIR design with quantised coefficients
Equaliser tap solution	Least squares	Normal equations, QR	MMSE equaliser initialisation
Bit allocation	Integer, convex relaxation	Water-filling then rounding	OFDM loading, quantisation budgeting
Scheduling / binding	NP-hard	ILP, list scheduling, force-directed	HLS internals
Retiming	Polynomial	Leiserson–Saxe	Timing optimisation
Placement	NP-hard	Analytic + partitioning	Physical design
Layer/schedule ordering	Combinatorial	Local search, simulated annealing	LDPC layered decoding order
Word-length assignment	Mixed integer	Heuristic + simulation	Fixed-point conversion

The objective function must be the true cost, not a convenient proxy. A measured example: optimising an LDPC layer ordering against a closed-form stall estimate produced a schedule that a cycle-accurate model scored differently — the formula predicted 108 stall cycles where the true figure was 80. Because the formula is an upper bound that assumes every potential conflict materialises, it ranks schedules incorrectly, and the search converges on the wrong one. **Build the accurate evaluator before the optimiser;** a search is only as good as the function it is minimising, and a fast wrong objective is worse than a slow right one.

Table 102. Numerical methods and their hardware suitability

Method	Convergence	Hardware note
Newton–Raphson	Quadratic	Needs a multiplier and a good seed; used for reciprocal and rsqrt
Goldschmidt	Quadratic	Better pipelining than Newton (no dependency chain)
CORDIC	Linear (one bit per iteration)	Shifts and adds only
Polynomial (minimax)	Fixed degree	Remez-fitted polynomials beat Taylor for equal degree
Piecewise polynomial + LUT	—	The usual production answer
Iterative refinement	Doubles accuracy per step	Limited by conditioning — see A5.2

Graduate · Taylor series should almost never appear in shipped hardware. A Taylor expansion minimises error at a single point and degrades away from it; a minimax (Remez) polynomial of the same degree distributes error evenly and typically achieves the same worst-case accuracy with one or two fewer terms. Since each term is a multiply–add, that is a direct area and latency saving. The standard production recipe is: reduce the argument to a small interval using the number's exponent, evaluate a low-degree minimax polynomial on that interval, then reconstruct. **Knowing that the textbook series is the wrong tool is a small piece of knowledge with a consistently measurable payoff.**

I4. Discrete Mathematics and Graphs in Hardware

Table 103. Graph problems in the design flow

Problem	Where it appears	Complexity	Practical method
Topological sort	Netlist evaluation, scheduling	Linear	Exact
Longest path	Static timing analysis	Linear on a DAG	Exact — this is what STA computes
Cycle detection	Combinational loop check	Linear	Exact
Min-cut / max-flow	Partitioning, retiming	Polynomial	Exact
Graph colouring	Register allocation, channel assignment	NP-hard	Heuristic
Clique / independent set	Binding in HLS	NP-hard	Heuristic
Shortest path	Routing	Polynomial	A*, maze routing
Steiner tree	Multi-pin net routing	NP-hard	Heuristic
Isomorphism	LVS (layout vs schematic)	Unknown class	Practical algorithms

Graduate · Recognising that a design task is a known graph problem is worth more than knowing an algorithm for it. Static timing analysis is longest path on a DAG — which is why combinational loops must be forbidden: they make the problem ill-posed, not merely difficult. Retiming is a min-cost flow problem, which is why it is exactly solvable while placement (a quadratic assignment problem) is not. **The tractability boundary explains the tool landscape:** tasks on the polynomial side have exact tools that engineers trust, and tasks on the NP-hard side have heuristics whose results engineers must inspect. A designer who knows which side a problem lies on knows whether to argue with the tool.

Table 104. Boolean algebra and representations

Representation	Property	Use
Truth table	Exponential size	Small functions, LUT mapping
SOP / POS	Two-level	PLA, simple synthesis
BDD	Canonical for a fixed variable order	Equivalence checking ; order-sensitive size
AIG (And-Inverter Graph)	Compact, not canonical	Modern synthesis and formal engines
CNF + SAT	—	Bounded model checking, equivalence
SMT	Theories beyond Boolean	Word-level formal verification

Graduate · **The shift from BDDs to SAT reshaped formal verification.** BDDs are canonical, which makes equivalence a pointer comparison, but their size explodes for arithmetic functions such as multipliers and is acutely sensitive to variable ordering. Modern SAT solvers, with conflict-driven clause learning, handle far larger instances without canonicity. The practical consequence for an IP engineer is that **formal property checking is now feasible on real control logic** — arbiters, FIFOs, protocol adapters, FSM reachability — where a decade ago it was a specialist activity. It remains infeasible on deep datapaths, so the division of labour is: formal for control, simulation with a golden model for datapath. **Knowing which side of that line a block falls on is how a verification plan is written.**

J1. On-Chip Memory

Table 105. Memory types available to an IP block

Type	Bit cell	Density	Notes
6T SRAM	6 transistors	High	Standard; compiled by the foundry
8T / 10T SRAM	8–10 T	Lower	Better read stability, low-voltage operation
Register file	Latch or flop array	Low	Multi-port, fast, expensive
Flip-flop array	—	Lowest	Synthesisable — the only portable option for small storage
Dual-port SRAM	8T	Lower	True dual port costs ~30–40% more area
Pseudo dual port	6T, time-multiplexed	High	Half the bandwidth
ROM	—	Very high	Constants, microcode, S-boxes
eDRAM / MRAM / RRAM	—	Very high	Process-specific; limited availability

Graduate · **For an IP vendor the portability question dominates the density question.** A compiled SRAM is smaller and faster than a flip-flop array, but it is a foundry-specific macro: shipping RTL that instantiates one ties the customer to a particular process and library. The standard resolution is a **memory wrapper** — the IP instantiates a thin module with a defined interface, and the customer maps it to their compiler's output or to a behavioural model. A well-built IP ships the wrapper, a synthesisable fallback, and a document specifying the required timing (read latency, write behaviour on a read–write collision). **Omitting the collision behaviour is a frequent and expensive omission**, because different compilers do different things and the block's correctness may depend on which.

Table 106. Memory design considerations

Issue	Consequence	Handling
Read/write collision	Behaviour is compiler-dependent	Specify it ; forbid it in the design if possible
Banking	Enables parallel access	Address mapping becomes a design choice
Wide words vs many banks	Power and area trade	Follow the access pattern
ECC	Soft-error protection	Adds a cycle of latency and ~12–25% bits
Scrubbing	Corrects accumulated errors	Background read–correct–write
Redundancy and repair	Yield	Foundry feature; needs BIST/BIRA
Retention voltage	Low-power state	Below it, data is lost

Graduate · **ECC on memory is a reliability calculation, not a preference.** Soft-error rate is quoted in FIT per megabit (failures in 10^9 device-hours), typically a few hundred FIT/Mb at sea level for SRAM. A 10 Mb on-chip memory at 300 FIT/Mb gives 3000 FIT, or roughly one upset per 38 years per device — negligible for a phone, unacceptable for a fleet of a million servers, where it means an upset every twenty minutes somewhere in the fleet. **The same silicon needs ECC in one market and not in another**, which is why it must be a parameter rather than a fixed design choice, and why the datasheet must state the FIT contribution with and without it.

J2. Accelerators: Systolic Arrays and the Roofline

Left of the ridge, adding compute units buys nothing

Figure 13. The roofline model. A kernel's arithmetic intensity determines whether more compute or more bandwidth helps.

$$\text{Attainable performance} = \min(\text{Peak compute}, \text{Bandwidth} \times \text{Arithmetic intensity})$$

Graduate · **The roofline is the first slide of any accelerator proposal, and it decides the architecture.** Arithmetic intensity — useful operations per byte moved from memory — is a property of the algorithm and its dataflow, not of the hardware. A naive matrix multiply that re-reads operands has low intensity and is memory-bound: adding multipliers achieves nothing. Tiling the computation so that each loaded element is reused n times multiplies the intensity by n and moves the kernel rightward past the ridge, at which point additional compute finally pays. **Every accelerator architecture is, at bottom, a scheme for raising arithmetic intensity.**

Each datum is read from memory once and reused across the array

Arithmetic intensity rises with array size — that is the whole point

Figure 14. A systolic array. Operands flow through the array and are reused by every processing element they pass.

Table 107. Accelerator dataflow taxonomy

Dataflow	What stays resident	Best when
Weight stationary	Weights in the PE	Weights are reused across many activations (CNN inference)
Output stationary	Partial sums in the PE	Long reduction chains; minimises partial-sum movement
Row stationary	A row of the convolution	Balances all three reuse types
No local reuse	Nothing	Simple, memory-bound

Table 108. Precision in inference accelerators

Format	Bits	Effect	Hardware cost
FP32	32	Baseline	Reference
BF16	16	Same exponent range as FP32, fewer mantissa bits	~1/2 multiplier area; drop-in for training
FP16	16	Smaller range — needs loss scaling	~1/2
INT8	8	Requires calibration or QAT	~1/4 area, ~1/4 energy of FP32
INT4 / INT2	4/2	Significant accuracy loss without care	Smaller still
Binary / ternary	1–2	XNOR–popcount replaces multiply	No multipliers at all
Mixed / per-channel scale	—	Recovers most INT8 accuracy	Per-channel scaling logic

Graduate · Binary networks replace arithmetic with logic, which changes the whole cost structure. When weights and activations are ± 1 , a multiply becomes an XNOR and the accumulation becomes a population count. A 256-input dot product is then 256 XNOR gates and a popcount tree — a few hundred gates instead of 256 multipliers. The trade is accuracy, recovered partially by keeping the first and last layers at higher precision and by batch normalisation folded into a threshold

comparison. **For an IP house this is attractive because the resulting block is small, fully synthesisable, and has no dependence on DSP hard macros**, which makes it portable across FPGA and ASIC targets.

Table 109. Accelerator interface decisions

Decision	Options	Consequence
Weight delivery	Resident in the bitstream vs streamed at run time	Dominates the system architecture: bandwidth vs flexibility
Granularity	Layer-at-a-time vs fused layers	Fusion removes intermediate memory traffic
Control	Fixed sequence vs programmable	Flexibility vs area
Memory	Scratchpad vs cache	Scratchpad is deterministic; cache is easier to program
Sparsity	Dense vs structured vs unstructured	Unstructured sparsity rarely pays in hardware

J3. On-Chip Interconnect and Networks

Table 110. Interconnect topologies

Topology	Scaling	Latency	Use
Shared bus	Poor beyond ~8 masters	Low	Small SoC
Crossbar	$O(N^2)$ area	Low	Moderate port counts
Mesh NoC	Good	$O(\sqrt{N})$ hops	Many-core
Torus	Good	Lower diameter	—
Ring	Simple	$O(N)$	Moderate core counts
Tree / fat tree	Good for hierarchical traffic	—	Cache hierarchies
Butterfly / Clos	Good	Uniform	Switches

Table 111. NoC design issues

Issue	Cause	Solution
Deadlock	Cyclic dependency among buffers	Virtual channels, turn-model routing (e.g. dimension-order)
Livelock	Packets circulate without progress	Bounded misrouting, ageing
Head-of-line blocking	One blocked packet stalls the queue	Virtual channels
Fairness	Some sources starve	Arbitration policy
QoS	Mixed traffic classes	Priority virtual channels, rate limiting
Flow control	Buffer overflow	Credit-based

Graduate · **Deadlock freedom is a structural property and should be established structurally, not tested.** Dimension-order routing (traverse X fully, then Y) makes cyclic buffer dependencies impossible in a mesh, and the argument is a short proof rather than a simulation campaign. Adaptive routing performs better under load but reintroduces the possibility, which is then removed by reserving an escape virtual channel that uses dimension-order. **This is an unusually clean example of the general principle that architecture should make undesirable states unreachable rather than merely unlikely** — the same principle behind sparse FSM encodings and Gray-coded FIFO pointers.

Table 112. Chip-to-chip and chiplet interfaces

Standard	Scope	Note
PCIe	Board-level, packetised	Gen6 uses PAM4 and FLIT mode
CXL	Cache-coherent over PCIe PHY	Memory expansion and pooling
UCIe	Die-to-die in a package	Very short reach → very low energy per bit
BoW / AIB	Die-to-die	Open alternatives
HBM	Memory via silicon interposer	Very wide, moderate rate
Ethernet	Rack and beyond	—

Graduate · **Chiplets change the economics that an IP business operates in.** When a system is partitioned across dies, the interface between them becomes a standardised product boundary, and a company can sell an entire die rather than an RTL block. Energy per bit is the defining metric: on-chip wires are ~0.1 pJ/bit, UCIe die-to-die ~0.5 pJ/bit, and long-reach SerDes ~5–10 pJ/bit. **That two-order-of-magnitude spread is why partitioning decisions are made at the package level and why**

die-to-die PHY IP became valuable so quickly. A digital design house cannot build the PHY, but the link layer, the retry and CRC logic, and the protocol adapters above it are all synthesisable — the familiar pattern of a sellable digital block adjacent to an unreachable analogue one.

J4. Image and Video Coding

Table 113. Codec pipeline stages

Stage	Purpose	Hardware character
Prediction (intra)	Exploit spatial correlation	Many modes → mode decision is a search
Prediction (inter / motion)	Exploit temporal correlation	Motion estimation dominates encoder cost
Transform	Energy compaction (integer DCT)	Multiplier-free integer approximations
Quantisation	Lossy step — rate control lives here	Divide by a table value
Entropy coding	Remove remaining redundancy (CABAC)	Serial bottleneck
Loop filter (deblocking, SAO, ALF)	Remove artefacts	In the reconstruction loop — must be bit-exact
Reference frame store	—	DRAM bandwidth dominates

Graduate · **Encoder and decoder are asymmetric by design.** The standard specifies only the decoder; the encoder may choose modes however it likes, provided the bitstream is conformant. This means **encoder quality is a product differentiator while decoder correctness is a conformance requirement**, and the two have completely different verification strategies: a decoder is verified against conformance bitstreams with bit-exact expected output, whereas an encoder is evaluated on rate-distortion curves and must only produce decodable output. A design house entering video should know which side it is selling into, because the effort profiles differ by an order of magnitude.

Table 114. Standards and their distinguishing features

Codec	Year	Key additions	Hardware impact
JPEG	1992	8×8 DCT, Huffman	Simple, still ubiquitous
H.264/AVC	2003	Integer transform, CABAC, variable block size	Integer transform removes encoder/decoder drift
HEVC/H.265	2013	CTU up to 64×64, 35 intra modes, SAO	Much larger mode search
VP9 / AV1	2013/2018	Royalty-free, ANS coding, many partitions	Very large encoder search space
VVC/H.266	2020	More partitions, ALF, affine motion	Further complexity
JPEG XS / light-weight	—	Low latency, visually lossless	Line-based, small buffers — a good niche for a small IP house

Bit-exactness inside the reconstruction loop is non-negotiable. The decoder's output feeds the encoder's prediction, so any arithmetic difference accumulates frame after frame — drift. This is why every in-loop operation (transform, quantisation, interpolation filters, deblocking) is specified as exact integer arithmetic with defined rounding, and why a reference model for a codec must reproduce those operations bit for bit rather than mathematically. **A floating-point reference model of a video codec is not a reference model.**

K1. Wireless Physical Layers

K1.1 OFDM

Cyclic prefix $\geq$ channel delay spread

$\Rightarrow$ multipath becomes circular convolution

$\Rightarrow$ one complex tap per subcarrier equalises the channel

The CP converts a hard equalisation problem into a division

Figure 15. OFDM transmitter. The cyclic prefix is the trick that makes frequency-domain equalisation valid.

Graduate · Why the cyclic prefix works, stated precisely. A linear convolution with the channel is not diagonalised by the DFT; a *circular* convolution is. Prepending the last N_{cp} samples of the symbol makes the channel's linear convolution look circular to the receiver, provided N_{cp} exceeds the channel's delay spread. The channel matrix then becomes diagonal in the DFT basis, so equalisation reduces to dividing each subcarrier by one complex number. **An N -tap time-domain equalisation problem has been exchanged for N_{cp}/N of lost throughput.** That trade is the entire justification for OFDM, and it explains why the CP length in every standard is tied to the expected delay spread of its deployment environment.

Table 115. OFDM impairments and their remedies

Impairment	Effect	Remedy	Where implemented
PAPR	Sum of subcarriers has a high peak	Clipping, tone reservation, SLM; or use SC-FDMA uplink	Digital pre-distortion; amplifier back-off
Carrier frequency offset	Destroys subcarrier orthogonality (ICI)	Estimate from preamble/pilots, correct before FFT	Digital
Sampling clock offset	Progressive phase rotation	Track with pilots	Digital
Phase noise	Common phase error + ICI	Estimate CPE from pilots	Digital
I/Q imbalance	Mirror-image interference	Estimate and compensate	Digital
Doppler	Time-varying channel within a symbol	Shorter symbols, or per-symbol tracking	Design-level

Graduate · Frequency offset is the impairment that must be fixed first and fixed well. A residual offset destroys orthogonality and produces inter-carrier interference that no subsequent equaliser can undo, because the subcarriers are no longer separable. The tolerance is roughly 1% of the subcarrier spacing for negligible loss; in 5G NR with 30 kHz spacing that is 300 Hz — at 3.5 GHz carrier, under 0.1 ppm. **This single requirement sets the crystal specification for the whole device,** which is a good illustration of a digital-layer requirement propagating down to a bill-of-materials cost.

K1.2 MIMO

Table 116. MIMO techniques

Technique	Objective	Requirement	Processing
Spatial multiplexing	Throughput	Rich scattering	Matrix inversion or successive cancellation per sub-carrier
Space-time coding	Diversity	None	Simple combining (Alamouti)
Beamforming	SNR, interference	Channel knowledge at the TX	Weight computation
Massive MIMO	Both	Many antennas, reciprocity	Large matrix operations; Cholesky/QR territory
MU-MIMO	Multi-user capacity	Multi-user CSI	Precoding (ZF, MMSE, dirty paper)

Table 117. MIMO detection algorithms

Detector	Complexity	Performance	Hardware
Zero forcing	One matrix inverse	Noise enhancement	Cholesky on $H^H H$
MMSE	One matrix inverse	Better at low SNR	Same, with a regularising term
V-BLAST / SIC	Iterative	Better	Ordering + repeated inversion
Sphere decoding	Variable	Near-ML	Data-dependent latency — awkward
K-best	Fixed	Near-ML	Fixed latency — preferred in hardware
Belief propagation	Iterative	Good	Fits with LDPC decoding

Graduate · **K-best beats sphere decoding in hardware for a reason that has nothing to do with performance.** Sphere decoding prunes a search tree adaptively, so its runtime depends on the channel and the noise realisation; a pipelined receiver with a fixed symbol rate cannot accommodate variable latency without buffering for the worst case, which negates the saving. K-best keeps a fixed number of candidates at every level, giving constant throughput and latency at slightly worse error performance. **Determinism is worth more than average-case efficiency in a streaming datapath,** and this principle recurs in FEC (fixed iteration counts), in SVD (fixed sweep counts), and in CFAR (fixed window sizes).

K2. Protocol Stacks as Hardware

Table 118. Ethernet layering and what each layer does

Layer	Function	Hardware	Clause (802.3)
MAC	Framing, addressing, CRC, flow control	Digital	4, 31
RS-FEC	Reed–Solomon KP4/KR4	Digital — soft IP	91, 161
PCS	64b/66b or 256b/257b coding, scrambling, lane distribution, alignment markers, gearbox	Digital — soft IP	49, 82, 119
PMA	Serialisation, clock recovery, equalisation	Analogue/mixed — hard macro	—
PMD	Electrical or optical interface	Analogue	—
AN / LT	Auto-negotiation, link training	Digital + control	73, 72

Graduate · **The PCS/PMA boundary is the commercial boundary of the whole industry.** Vendors describe their products in exactly these terms — "hardened PMA with a soft PCS layer" — because the PMA is tied to a process node and must be delivered as a hard macro, while the PCS is process-independent RTL. For a digital design house this boundary defines what is reachable: everything from the PCS upward. It is also where the open-source landscape is thinnest — 10G BASE-R PCS exists in open form, but 100G-and-above multi-lane PCS and RS-FEC do not — which makes it a reasonable place to look for an entry product.

Table 119. 64b/66b coding: what each piece is for

Element	Purpose	Failure if omitted
2-bit sync header	Distinguishes data from control blocks	Receiver cannot find block boundaries
Self-synchronising scrambler ($x^{58} + x^{39} + 1$)	DC balance and transition density	Baseline wander through AC coupling; CDR loses lock
Block type field	Encodes control block layout	—
Block lock state machine	Finds the header position	No synchronisation
BER monitor	Counts invalid sync headers	No link quality signal
Gearbox	Maps 66 bits onto a 64-bit datapath	Rate mismatch — 66 does not divide the bus width

Graduate · **The gearbox is the piece newcomers underestimate.** A 66-bit block does not fit a 64-bit datapath, so the PCS must repack a 66-bit stream into 64-bit words, which realigns every block by two bits and returns to alignment only after 32 blocks. The resulting barrel shifter and control state machine are a surprisingly large fraction of the PCS. Multi-lane 100G+ adds alignment markers, lane deskew and reordering on top. **The "simple" coding layer is mostly plumbing, and the plumbing is where the engineering effort goes** — a pattern that recurs in every protocol block.

Table 120. PCIe layering

Layer	Function	Notes
Transaction (TLP)	Read/write/completion semantics, ordering rules	Ordering rules are subtle and a frequent source of bugs

Layer	Function	Notes
Data link (DLLP)	Sequence numbers, ACK/NAK, credit flow control	Replay buffer sizing matters
Physical logical	Encoding (8b/10b, 128b/130b, FLIT), scrambling, lane management	—
Physical electrical	SerDes	Hard macro
LTSSM	Link training state machine	Large, intricate FSM — a classic formal-verification target

Table 121. DDR memory interface

Element	Function	Difficulty
Command scheduling	Bank, row, column timing	Performance-critical
Training	Write levelling, read gate, per-bit deskew	Runs at boot; a mix of hardware and firmware
PHY	DLL/PLL, DQS strobing	Hard macro
ECC	SECEDED or chipkill	Latency and bandwidth cost
Refresh	Periodic; blocks access	Real-time guarantee impact
Rowhammer mitigation	Track and refresh victims	Security requirement

K3. Reliability, Safety and Yield

Table 122. Wear-out mechanisms

Mechanism	Physics	Accelerated by	Design response
NBTI / PBTI	Interface trap generation under gate bias	Voltage, temperature, duty cycle	Timing guard band; adaptive body bias
HCI	Hot carriers damage the oxide	Switching activity, high field	Reduce voltage; limit slew
TDD	Oxide breakdown	Field, temperature	Thickness rules; Weibull statistics
Electromigration	Momentum transfer moves metal atoms	Current density, temperature	Wire width rules, via arrays
Stress migration	Thermo-mechanical stress	Thermal cycling	Layout rules
Soft errors	Particle strikes	Altitude, neutron flux	ECC, TMR, scrubbing

Graduate · Wear-out is a timing constraint, not an afterthought. NBTI shifts $|V_{TH}|$ over the device lifetime, so a path that just met timing on day one may fail after five years. Sign-off therefore uses an aged library or an explicit derate — commonly 5–10%. For an IP vendor this matters in a specific way: **a frequency claim is implicitly a claim about a lifetime**, and the two must be quoted together. "500 MHz" at fresh silicon and "500 MHz over ten years at 125 °C" are different products.

Table 123. Functional safety (ISO 26262) concepts

Concept	Meaning	Hardware implication
ASIL A–D	Risk classification	D is the most stringent
SPFM	Single-point fault metric	≥99% for ASIL D
LFM	Latent fault metric	≥90% for ASIL D
PMHF	Probabilistic metric for random hardware failures	<10 FIT for ASIL D
Safety mechanism	Detects or controls a fault	ECC, lockstep, watchdogs, BIST
Diagnostic coverage	Fraction of faults detected	Drives the metrics
Lockstep	Duplicate cores compared cycle by cycle	Delayed lockstep avoids common-cause failures
FMEDA	Failure mode and diagnostic analysis	A required deliverable for safety IP

Safety certification changes the deliverable list, not just the design. An ASIL-D block must ship with an FMEDA showing computed SPFM, LFM and PMHF, a safety manual stating the assumptions of use, and evidence of a qualified development process. A technically excellent block without these documents cannot be used in a safety application at any price. **For a small design house this is the clearest example of a market that is closed not by engineering capability but by process obligations**, and it should be entered deliberately or not at all.

Table 124. Yield

Concept	Expression	Meaning
Defect density D_0	defects/cm ²	Process maturity
Poisson yield	$Y = e^{-AD_0}$	Pessimistic for large dies
Negative binomial	$Y = (1 + AD_0/\alpha)^{-\alpha}$	Accounts for defect clustering
Die area effect	—	Yield falls steeply with area — the economic driver behind chiplets

Concept	Expression	Meaning
Repair / redundancy	—	Spare rows and columns in memories raise yield
Parametric yield	—	Devices that work but miss specification

K4. Current Research Directions

This chapter surveys the areas where current literature is active, so that a reader who has absorbed the preceding chapters can approach a recent paper knowing what problem it is addressing and which established constraint it is trying to relax.

Table 125. Active areas and the constraint each attacks

Area	Constraint attacked	Approach	Open problem
Post-quantum cryptography	Shor's algorithm breaks RSA/ECC	Lattice (ML-KEM/ML-DSA), hash-based (SLH-DSA)	Large keys; NTT throughput; side-channel protection of lattice arithmetic
In-memory computing	Von Neumann data movement energy	Analogue MAC in memory arrays (RRAM, SRAM)	ADC overhead often cancels the saving; device variability
Approximate computing	Exactness is expensive	Truncated multipliers, stochastic computing, voltage overscaling	Error bounds must be guaranteed, not measured
Chiplets / UCle	Reticle limit and yield vs die area	Disaggregation with standard die-to-die links	Test, thermal, known-good-die
Nonlinear equalisation	Linear equalisers fail on nonlinear channels	Volterra series, neural equalisers	Power and latency; verification of a learned block
Concatenated FEC for 224G	KP4 alone insufficient at 200G/lane	Outer RS-KP4 + inner Hamming(128,120)	Latency budget; decoder complexity
Formal at scale	Simulation cannot cover state space	Word-level model checking, SMT	Datapath equivalence remains hard
ML for EDA	Heuristics in placement/routing	Learned cost models, RL for scheduling	Reproducibility and trust in sign-off
Open PDK / open EDA	Tool licence cost as a barrier	SkyWater/IHP PDKs, OpenROAD, Yosys	Analogue and advanced-node support
Cryogenic and superconducting	CMOS energy floor	SFQ logic, cryo-CMOS	Infrastructure; interface to room temperature

Graduate · How to read a paper in any of these areas. Each row names a constraint from earlier chapters. In-memory computing attacks the roofline's memory-bound region (J2); approximate computing attacks the fixed-point accuracy–area trade (A3, C1); neural equalisation attacks the linear-model assumption behind every equaliser in F1; chiplets attack the yield-versus-area relation in K3. **Identifying which constraint a paper is relaxing, and what it pays for the relaxation, is a faster route to understanding than reading the method first** — and it immediately tells you whether the result transfers to your own problem, because you know which assumption it depends on.

A caution that applies to all of these areas. Reported gains are measured at an operating point the authors chose. Before accepting a claim, locate three things: the baseline (is it a strong implementation or a straw man?), the operating conditions (process, voltage, data set, channel), and the point at which the advantage disappears. A result quoted without the crossover point is a data point, not a design rule — and in an IP business, mistaking one for the other is how a year is lost.

L1. Semiconductor Physics: What Survives into Design

Doping moves the Fermi level; the band gap sets the intrinsic carrier density

Figure 16. Band structure. The gap determines whether a material conducts, and silicon's 1.1 eV gap is what makes it useful.

Table 126. Physical quantities and where a designer meets them

Quantity	Symbol / value	Design consequence
Band gap of Si	1.12 eV at 300 K	Falls with temperature $\rightarrow$ leakage rises, V_{TH} falls
Intrinsic carrier density	$n_i \approx 10^{10} \text{ cm}^{-3}$	Doubles roughly every 8 K $\rightarrow$ junction leakage doubles with it
Thermal voltage	$kT/q = 25.9 \text{ mV}$ at 300 K	Sets the subthreshold slope: 60 mV/decade minimum
Mobility μ	$\approx 1400 \text{ (e)}, 450 \text{ (h)} \text{ cm}^2/\text{Vs}$	Why PMOS is sized $\sim 2\text{--}3\times$ wider than NMOS
Saturation velocity	$\approx 10^7 \text{ cm/s}$	Short-channel current becomes linear in overdrive
Oxide capacitance	$C_{ox} = \epsilon_{ox}/t_{ox}$	Thinner oxide $\rightarrow$ more drive and more gate leakage
Depletion width	$\propto \sqrt{(V/N)}$	Short-channel effects; junction capacitance

Graduate The 60 mV/decade subthreshold slope is a hard physical limit and it ended Dennard scaling. Below threshold, drain current depends exponentially on gate voltage with a slope of at best $(kT/q) \ln 10 \approx 60 \text{ mV}$ per decade at room temperature, because the mechanism is thermal emission over a barrier. To keep leakage constant while lowering the supply, the threshold must fall by the same amount — but each 100 mV of threshold reduction multiplies leakage by about fifty. **This is why supply voltage stopped scaling near 0.8 V and why power density rose**, which in turn is why the industry turned to specialised accelerators and therefore why the IP market grew. A thermodynamic constant is visible in a business model.

Table 127. Devices beyond the planar MOSFET

Device	Principle	Motivation
FinFET	Gate wraps a vertical fin on three sides	Better electrostatic control $\rightarrow$ less DIBL and leakage
GAA / nanosheet	Gate surrounds the channel completely	Further control; width quantised by sheet count

Device	Principle	Motivation
FD-SOI	Thin body on buried oxide	Low leakage; body bias as a live tuning knob
Tunnel FET	Band-to-band tunnelling	Can beat 60 mV/decade ; low on-current so far
Negative-capacitance FET	Ferroelectric gate stack	Internal voltage amplification; reliability unproven
2D materials	MoS ₂ and similar	Ultra-thin body; research stage

L2. Power Delivery and Conversion

Table 128. Voltage regulator types

Type	Efficiency	Ripple	Re- sponse	Where
LDO	V_{out}/V_{in} — poor if the drop is large	Very low	Fast	Sensitive analogue, small currents
Buck (switching)	85–95%	Higher (switching ripple)	Slower	Digital cores, large currents
Boost	—	—	—	Raising a voltage
Charge pump	Moderate	—	—	Small currents, no inductor
Integrated voltage regulator	—	—	Very fast	Per-domain DVFS on die
Switched-capacitor	Good at fixed ratios	—	—	On-die, no inductor needed

Graduate · Regulator response time is a digital design constraint. When a large synchronous block starts, it draws a current step; the regulator takes time to respond, and during that time the supply droops. The droop reduces gate drive and therefore increases delay, which can violate timing. Designers respond with **di/dt management** — staggering the release of clock gates so a block wakes in stages rather than all at once. **This is a purely digital technique introduced to solve an analogue problem, and it must be specified:** an IP that draws its full current in one cycle after an enable is harder to integrate than one that ramps.

Table 129. Decoupling hierarchy

Level	Capacitance	Effective range	Limit
On-die (MOS, MIM)	nF	>100 MHz	Area
Package	μF	10–100 MHz	Package inductance
Board ceramic	μF	1–10 MHz	ESL
Bulk electrolytic	100 μF+	<1 MHz	—
Anti-resonance	—	50–200 MHz typically	Where package L resonates with die C — must be damped

The anti-resonance peak is a common cause of otherwise inexplicable failures. Package inductance and on-die capacitance form a parallel resonance at which the power delivery network's impedance is much higher than at neighbouring frequencies. A workload whose current draw happens to contain energy at that frequency — a loop running at the resonant rate, a burst-mode accelerator — produces supply noise far larger than the average current would suggest. The symptom is a design that passes all tests but fails on one specific piece of software. **A digital block's current spectrum, not only its average power, is a system-level property.**

L3. Thermal and Packaging

$$T_{junction} = T_{ambient} + P \cdot \theta_{JA}$$

Table 130. Thermal resistance path

Segment	Symbol	Typical	Improved by
Junction to case	θ_{JC}	0.1–1 K/W	Die attach, lid material
Case to heatsink	—	0.1–0.5 K/W	Thermal interface material
Heatsink to ambient	θ_{SA}	0.5–10 K/W	Fin area, airflow
Total	θ_{JA}	—	—
Hot spot	—	—	Local power density, not average — floorplanning matters

Graduate · **Hot spots are a floorplanning problem, and they couple back into timing.** Average die temperature may be comfortable while a dense arithmetic block runs 20 K hotter than its surroundings. Since delay and leakage both depend on temperature, that block is slower and leakier than the sign-off corner assumed, and its leakage raises its temperature further — a positive feedback known as thermal runaway in the extreme. The design responses are spreading high-activity logic, inserting thermal sensors and throttling, and accounting for the gradient in timing analysis. **For an IP vendor, a block with very high local power density should say so**, because the customer's floorplanner needs to know.

Table 131. Package types

Package	Density	Thermal	Use
Wire-bond QFN/BGA	Low	Moderate	Cost-sensitive
Flip-chip BGA	High	Good (heat exits through the lid)	High performance
Silicon interposer (2.5D)	Very high	Good	HBM integration
3D stacking	Highest	Difficult — heat is trapped	Memory on logic
Fan-out wafer level	High	Moderate	Mobile
Chiplet in package	High	Manageable	Disaggregated designs

Graduate · **Thermal constraints are what limit 3D integration, not manufacturing.** Stacking a logic die under another die places its heat behind a thermal barrier, so the achievable power density falls sharply. This is why current 3D products stack memory (low power) on logic rather than logic on logic, and why thermal modelling now appears early in architecture rather than at the end. **The physical constraint determines the partitioning, which determines which interfaces are needed, which determines which IP is valuable.**

L4. Feedback and Control

Feedback loops appear throughout an IP portfolio: PLLs, CDRs, adaptive equalisers, AGC, DVFS controllers, thermal throttling, and the convergence of iterative decoders. The same small set of concepts governs all of them.

Table 132. Control concepts and their hardware instances

Concept	Meaning	Instance
Open-loop gain	Gain around the loop	PLL $K_{PD}K_{VCO}$
Loop bandwidth	Where gain crosses unity	The central design parameter of every loop
Phase margin	Phase at crossover, relative to -180°	$<45^\circ$ gives peaking and ringing
Type / order	Number of integrators / poles	Type-2 PLL tracks a frequency step with zero error
Damping ζ	—	$\zeta=0.707$ is the usual target
Steady-state error	—	Determines whether an offset persists
Settling time	—	Lock time; adaptation time
Discrete-time effects	Sampling and delay in the loop	Digital loops must include their own latency

Latency inside a digital loop is a stability problem, not merely a performance one. A digital adaptation loop that computes an error, pipelines it through several stages, and then applies a correction has inserted pure delay, which subtracts phase without reducing gain — exactly what destroys phase margin. The loop can oscillate even though every block in it is correct. The standard remedies are to reduce the loop gain (slower adaptation), to shorten the loop, or to compensate explicitly. **A model that applies the correction instantaneously will not show the instability**, so the pipeline delay must be in the model. This is one of the most common gaps between a working model and non-working hardware.

Table 133. Adaptation loops in a receiver and their interactions

Loop	Controls	Typical bandwidth	Interacts with
AGC	Input amplitude	Fast	Everything downstream
CDR	Sampling phase	Moderate	Equaliser — MM lock point depends on it
CTLE adaptation	Analogue peaking	Slow	FFE
FFE/DFE adaptation	Tap weights	Slow	CDR
Offset calibration	Comparator offsets	Very slow	Slicer thresholds
Interleaving calibration	ADC mismatch	Very slow	All of the above

Graduate · Six loops sharing one signal is the hardest part of a modern receiver, and it is a systems problem rather than a circuit one. Each loop is stable alone; together they can hunt, lock to a wrong point, or fail to converge from certain initial conditions. The standard engineering response is **bandwidth separation** — giving each loop a rate an order of magnitude apart so that faster loops appear instantaneous to slower ones and slower loops appear constant to faster ones — plus a defined start-up sequence. **Both the separation and the sequence belong in the specification**, and verifying convergence from adverse initial conditions is a system-model task that no block-level testbench will perform.

M1. The Hardware–Software Interface

An IP block is useless until software can drive it. The interface between them is a design artefact in its own right, and getting it wrong produces integration cost that dwarfs the block's development.

Table 134. Interface mechanisms

Mechanism	Direction	Cost	When appropriate
Memory-mapped registers	CPU → block	Low	Configuration, status; the default
Polling	CPU reads status	Wastes CPU cycles and power	Very short operations
Interrupt	block → CPU	Latency and context switch	Completion of long operations
DMA	block ↔ memory	Bus bandwidth	Bulk data; avoids CPU copying
Descriptor rings	—	Memory traffic	Streaming with many buffers (network, storage)
Mailbox / doorbell	bidirectional	Low	Command submission
Shared memory + fences	—	Coherence traffic	Tight coupling; requires a memory model

Graduate · **The single most consequential interface decision is who moves the data.** A block that requires the CPU to write its input and read its output word by word can be limited by the CPU even when the block itself is fast; a DMA-capable block moves data in bursts and leaves the CPU free. The difference is frequently an order of magnitude in system throughput, and it is invisible in block-level benchmarks. **For an IP vendor this means the example design matters as much as the block:** a customer who integrates it through programmed I/O will measure disappointing performance and conclude the IP is slow.

Table 135. Register map design rules

Rule	Reason
Generate RTL, header, documentation and tests from one source	Three hand-maintained copies always diverge
Reserve and document unused bits	Forward compatibility
Make read-clear and write-one-clear behaviour explicit	Ambiguity here produces lost interrupts
Provide an identification and version register	Software can adapt to the actual hardware
Group by function, align to natural boundaries	Simplifies access
Avoid side effects on read where possible	A debugger that dumps registers must not change behaviour
State atomicity for wide registers	Prevents tearing

Read side effects break debuggers, and the failure is baffling when it happens. If reading a FIFO status register pops an entry, then attaching a debugger that displays the register window silently consumes data, and the bug disappears when the debugger is detached. Where a read side effect is genuinely required — a pop-on-read data port, for example — it must be isolated in its own register and clearly marked, so that a debug tool can be told to avoid it. This is a small documentation duty with a disproportionate payoff.

Table 136. Driver and firmware concerns an IP vendor should anticipate

Concern	What the IP must provide
Initialisation sequence	Exact required order, including any wait conditions
Reset semantics	What a soft reset does and does not clear
Error reporting	Sticky status bits with a defined clearing mechanism
Concurrency	Which registers may be accessed while the block is running
Endianness and bit order	Stated explicitly
Timeouts	Maximum time any operation can take
Low-power entry/exit	Sequence and state retention

M2. Machine Learning Hardware

Table 137. Operations that dominate inference

Operation	Share of compute	Arithmetic intensity	Hardware mapping
Convolution	High in CNNs	High with tiling	Systolic array or vector units
Matrix multiply (GEMM)	Dominant in transformers	High	The universal accelerator primitive
Attention (QK^TV)	Dominant in LLMs	Moderate	Memory bound at long sequence lengths
Element-wise / activation	Low compute	Very low	Memory bound; fuse with the previous layer
Normalisation	Low	Low	Fuse; needs reductions
Softmax	Low	Low	Needs exp and a reduction; numerically delicate
Embedding lookup	—	Very low	Random memory access

Graduate · **Fusion is the main architectural lever and it follows directly from the roofline.** An activation function performs one operation per element and therefore has arithmetic intensity near zero — it is entirely memory bound. Executed as a separate pass it costs a full read and write of the tensor. Fused into the preceding matrix multiply's output stage it costs essentially nothing. Real accelerators therefore expose fused operations rather than primitive ones, and their compilers spend most of their effort deciding what to fuse. **An IP block that implements a single layer type in isolation will underperform in a system for reasons that have nothing to do with its internal quality.**

Table 138. Quantisation approaches

Approach	Accuracy loss	Effort	Hardware
Post-training, per-tensor INT8	Moderate	Low	One scale per tensor
Post-training, per-channel INT8	Small	Low	Per-channel scale multiply — usually worth it
Quantisation-aware training	Very small	High	Same as above
INT4 with grouping	Noticeable	High	Group-wise scales
Mixed precision	Small	Moderate	Sensitive layers kept wider
Binary / ternary	Large	High	XNOR-popcount; no multipliers

Graduate · **Quantisation is a fixed-point problem and the vocabulary of Chapter A3 applies unchanged.** A per-tensor scale is a single Q format for the whole tensor; per-channel scaling is the recognition that different channels have different dynamic ranges, which is exactly the block-floating-point idea from the FFT chapter. Understanding this correspondence prevents an engineer from treating ML quantisation as a separate discipline: the questions — where to round, when to saturate, how dynamic range grows through a computation — are the same, and the answers are reached the same way.

Table 139. Sparsity

Kind	Speedup potential	Hardware feasibility
Unstructured (random zeros)	High in theory	Poor — irregular access defeats the memory system
Structured (2:4, block)	Moderate	Good — regular indexing
Channel / filter pruning	Moderate	Excellent — it is just a smaller dense model
Activation sparsity (ReLU)	Moderate	Dynamic; needs run-time detection

Unstructured sparsity is the clearest case of a metric that does not translate into hardware. A paper reporting 90% of weights pruned implies a tenfold reduction in operations, but realising it requires indexing individual non-zeros, which destroys the regular access patterns that give an accelerator its efficiency. The achieved speedup is commonly a small fraction of the nominal one, and can be below unity. **Structured sparsity exists because hardware needs regularity more than it needs fewer operations** — a principle that recurs whenever an algorithmic saving is proposed.

M3. Image Signal Processing

Table 140. The ISP pipeline

Stage	Function	Why it is in hardware
Black level and defect correction	Sensor offset, dead pixels	Per-pixel rate
Lens shading correction	Vignetting	Per-pixel with a gain surface
Demosaic	Bayer → RGB	Neighbourhood operation at pixel rate
White balance	Illuminant compensation	Per-pixel gains
Colour correction matrix	Sensor → standard colour space	3×3 per pixel
Gamma / tone mapping	Perceptual encoding	LUT per pixel
Noise reduction	Spatial and temporal filtering	Line buffers dominate the area
Sharpening	Edge enhancement	Convolution
Scaling	Resize	Polyphase filter

Graduate · Line buffers, not arithmetic, determine ISP cost. A 5×5 neighbourhood operation at 4K resolution requires four lines of 3840 pixels each held on chip; at 12 bits per component that is roughly 184 kbit per stage before any compute. A pipeline with several such stages spends most of its silicon on storage. The architectural consequences are standard: process in tiles rather than full lines, fuse stages so that a neighbourhood is read once and used by several operations, and choose separable filters wherever possible. **This is the same memory-versus-compute analysis as the roofline of Chapter J2, applied to a different domain.**

Table 141. Colour and vision concepts that reach the hardware

Concept	Meaning	Implementation note
Bayer pattern	One colour per photosite	Demosaic must interpolate two of three
Colour space (sRGB, YCbCr)	—	YCbCr separates luma for chroma subsampling
Chroma subsampling (4:2:0)	Half resolution chroma	Exploits lower chroma acuity — halves the data
Gamma	Non-linear encoding	Must be undone before linear operations
HDR / tone mapping	Wide dynamic range compressed for display	Local operators need neighbourhood statistics
Rolling shutter	Rows exposed at different times	Motion artefacts; a system issue

Performing linear operations on gamma-encoded data is a persistent and quiet error. Gamma encoding is non-linear, so averaging two gamma-encoded pixels does not give the gamma encoding of their average. Scaling, blending and filtering must therefore be done in linear light, which means decoding before and re-encoding after. The visible symptom is subtly wrong brightness at edges — easy to miss in a test pattern and obvious on real images. **Specify the colour encoding of every interface**, in the same way and for the same reason that fixed-point formats must be specified.

M4. Measurement and Characterisation

Everything in this book that is stated as a number came from a measurement, and the difference between a useful number and a misleading one is usually in the method rather than the instrument.

Table 142. Instruments and what they actually measure

Instrument	Measures	Principal limitation
Oscilloscope	Voltage versus time	Bandwidth and probe loading
Real-time versus sampling scope	—	Sampling scopes need a repetitive signal
Spectrum analyser	Power versus frequency	Resolution bandwidth changes the displayed noise floor
Vector network analyser	S-parameters	Calibration plane definition
BER tester	Errors per bit	Time: 10^{-12} at 10 Gb/s takes ~100 s per point
Time interval analyser	Jitter statistics	Trigger accuracy
Logic analyser	Digital state	No analogue detail
Thermal camera	Surface temperature	Emissivity; not junction temperature
Power analyser / shunt	Current	Bandwidth versus resolution

Graduate · **Bathtub extrapolation exists because direct BER measurement does not scale.** Confirming 10^{-15} by counting errors would take days per operating point, which is impossible for a characterisation sweep. Instead the eye is scanned at several sampling phases, the error rate is measured where it is high enough to be quick, and the Gaussian random-jitter tails are extrapolated to the target BER. **The extrapolation is only valid if the random component really is Gaussian and has been correctly separated from the bounded deterministic component** — which is why jitter decomposition is a required capability rather than a convenience, and why a reported margin should always name the method.

Table 143. Characterisation practices

Practice	Reason
Sweep, do not spot-check	A single operating point can be unrepresentative or accidentally favourable
Confirm the operating point is healthy first	Measurements taken on a broken setup look plausible
Obtain the same quantity a second way	An independent estimate catches methodological errors
List the trivial explanations and rule each out by measurement	A result that could be an artefact is a hypothesis, not a finding
Record conditions with every number	Temperature, voltage, part, instrument, settings
Report the condition under which the claim fails	A claim with no stated failure condition is advertising

Four measurement failures, each of which produced a plausible number that meant nothing. Taking the slope of a pulse at its peak — which is zero by definition — and reporting it as a sensitivity. Measuring residuals at an operating point where BER was already 0.49, so the link carried no information. Asking a tool for the longest path in an entire netlist when the quantity of interest was the delay around one feedback loop. Reporting a lookup table's accuracy at an operating point where the feedback taps were so small that the loop was effectively inactive, so the table was never exercised. **In every case the instrument worked and the number was wrong, because the quantity measured was not the quantity intended.** The four rules above are written to prevent exactly these.

N1. Asynchronous and Globally Asynchronous Design

Synchronous design — one clock, one timing constraint — is overwhelmingly dominant because it makes timing analysis tractable. Asynchronous techniques remain relevant in three specific places, and knowing which is which prevents both over-application and blind avoidance.

Table 144. Asynchronous styles

Style	Timing assumption	Property	Practical use
Bundled data	Matched delay line models the logic	Simple, small	Local handshakes, self-timed SRAM
Dual-rail / QDI	None (delay insensitive)	Robust to any delay; ~2× area	Extreme reliability, some security uses
Micropipelines	Bundled	Elastic pipelines	—
GALS	Synchronous islands, async between	Avoids a global clock tree	The practically important case — multi-domain SoCs
Self-timed memory	Internal	Hidden from the user	Nearly all SRAM

Graduate · **GALS is what most engineers actually encounter, usually without the name.** Any SoC with several clock domains connected by asynchronous FIFOs is globally asynchronous and locally synchronous. Framing it that way is useful because it makes the design rules explicit: each island has its own timing closure, and every boundary between islands is a CDC problem requiring one of the techniques of Chapter C3. **The failure mode of an undisciplined multi-domain design is not a timing violation but an intermittent data corruption,** which is far harder to diagnose — which is why the boundaries must be enumerated and checked by a tool rather than by inspection.

Table 145. Where fully asynchronous logic is genuinely used

Application	Reason
SRAM internal timing	Self-timed sense amplifier control is faster than a clock
Security	No clock to glitch; power profile is less data-correlated
Ultra-low power / energy harvesting	No clock power when idle
Very wide dynamic voltage range	Works at whatever speed the supply allows
Reliability at extremes	Delay-insensitive circuits tolerate huge variation

The barrier to asynchronous design is tooling, not theory. Standard synthesis, static timing analysis, scan insertion and equivalence checking all assume a clock. An asynchronous block therefore needs custom flows, and — decisively for an IP vendor — the customer must be able to integrate, verify and test it in *their* flow. **An asynchronous block is usually unsellable as RTL for this reason alone,** regardless of its merits. Where the technique is used commercially it is nearly always hidden inside a hard macro with a synchronous interface.

N2. Physical Design in More Depth

Table 146. Placement and routing concerns

Concern	Cause	Symptom	Remedy
Congestion	More nets than routing tracks in a region	Routing failures, detours, timing loss	Spread cells, reduce utilisation, restructure logic
Timing/congestion conflict	Timing wants cells close; routing wants them apart	—	Iterate; sometimes an architectural change is needed
Antenna effect	Charge accumulation on a long metal segment during etch	Gate oxide damage	Diode insertion, layer jumping
Crosstalk delay and noise	Coupling between adjacent nets	Timing variation, glitches	Spacing, shielding, net ordering
Electromigration	Current density	Long-term failure	Wire widening, via arrays
IR drop	Grid resistance	Local slowdown	Grid strengthening, decap
Hold violations after CTS	Skew changes after the clock tree is built	—	Buffer insertion; usually many thousands

Graduate · **Utilisation is the number that governs the whole back-end schedule.** Utilisation — the fraction of core area occupied by cells — trades area against routability. Below roughly 60% a design routes easily and wastes area; above roughly 80% congestion begins to dominate and each iteration becomes slower and less predictable. A block delivered with a recommended utilisation lets the customer floorplan correctly the first time. **Omitting it is one of the common causes of "the IP does not meet timing in our flow"**, because the customer packed it at 85% while the vendor characterised it at 65%.

Table 147. Standard cell library concepts

Concept	Meaning	Selection consequence
Track height (e.g. 7.5T, 9T)	Cell height in routing tracks	Taller cells are faster and larger
Drive strength (X1, X2, X4...)	Transistor width multiplier	Higher drive for larger loads
Multi- V_{TH} (LVT/SVT/HVT)	Threshold variants	Leakage versus speed, per cell
Characterisation corner	PVT point of the timing data	Must match the sign-off corner
NLDM / CCS	Delay model fidelity	CCS is needed at advanced nodes
Engineering change order cells	Spare gates scattered in the layout	Enable metal-only fixes after tape-out

Graduate · **Spare cells are cheap insurance that is often omitted and then badly missed.** Scattering a small percentage of unused gates across the floorplan allows a post-silicon logic fix to be implemented by changing only the metal masks, which costs a fraction of a full mask set and weeks rather than months. The area cost is typically one or two percent. **The decision is made at floorplan time and cannot be revisited**, which is why it belongs on the checklist of Chapter W1 rather than being left to back-end judgement.

N3. Statistics for Silicon

Table 148. Variation sources

Source	Scale	Correlation	Handled by
Lot to lot	Global	Fully correlated on a die	Process corners
Wafer to wafer	Global	Correlated	Corners
Die to die	Global	Correlated	Corners
Within die, systematic	Local	Position dependent	Layout-dependent effects, proximity rules
Within die, random	Local	Uncorrelated	OCV / AOCV / POCV derating
Random dopant fluctuation	Per device	None	$\sigma \propto 1/\sqrt{WL}$ — matters most for small devices

Graduate · The distinction between correlated and uncorrelated variation is what makes modern timing analysis tractable. If every device on a path varied independently, a long path would average out and show *less* relative variation than a short one — which is exactly what statistical on-chip variation (POCV) captures, and why it recovers pessimism that flat derating throws away. Flat OCV applies the same percentage to every path regardless of depth, which over-penalises long paths and under-penalises short ones (making hold analysis optimistic). **The statistics are not a refinement; using the wrong model can make a design that signs off fail in silicon.**

Table 149. Statistical concepts used in characterisation

Concept	Use
Mean, σ , $\pm 3\sigma$	Basic spread; $3\sigma \approx 99.73\%$
6σ design	Memory bit cells — billions of instances require extreme tails to be safe
Importance sampling	Simulating a 6 σ failure directly is infeasible; bias the sampling and correct
Monte Carlo	General variation analysis
Design of experiments	Efficient exploration of many parameters
Regression / response surface	Build a fast surrogate model
Confidence intervals	A measurement without one is an anecdote
Process capability C_{pk}	Manufacturing margin

Graduate · Memory bit cells illustrate why tail statistics matter so much. A 100 Mbit memory contains 10^8 cells; for the chip to yield, the per-cell failure probability must be well below 10^{-8} , which corresponds to roughly 5.7σ . Plain Monte Carlo would need on the order of 10^9 simulations to see such an event, so importance sampling — deliberately sampling the tail and reweighting — is mandatory. **This is why memory design is a specialised discipline**, and why memories come from compilers rather than being drawn by hand.

N4. Optical Links and Photonics

Beyond a few metres of copper, electrical links become impractical and the industry switches to optics. The digital blocks on either side — the FEC, the PCS, the DSP — are the same kind of IP discussed throughout this book, which is why the domain deserves a chapter.

Table 150. Optical link components

Component	Function	Impairment introduced
Laser (DFB, VCSEL)	Source	RIN, chirp, temperature drift
Modulator (direct, EML, MZM)	Impress data on light	Extinction ratio, chirp, nonlinearity
Fibre (SMF, MMF)	Transport	Chromatic dispersion, modal dispersion, attenuation, nonlinearity
Photodiode (PIN, APD)	Detect	Shot noise; APD adds excess noise
TIA	Current to voltage	Noise; bandwidth
Coherent receiver	Recover amplitude and phase	Requires a local oscillator and heavy DSP

Table 151. Modulation and detection schemes

Scheme	Detection	Reach	DSP required
NRZ / PAM4 IM-DD	Direct (intensity only)	≤ 10 km	Equalisation, FEC — 802.3 territory
Coherent QPSK / 16-QAM	Coherent (amplitude and phase)	Long haul	Very heavy: CD and PMD compensation, carrier recovery
Probabilistic shaping	Coherent	Long haul	Shaping encoder/decoder

Graduate • **Chromatic dispersion compensation is where photonics becomes a large digital problem.** Different wavelengths travel at slightly different speeds in fibre, so a pulse spreads over distance — and over hundreds of kilometres the spread reaches hundreds of symbol periods. Compensating it optically requires dispersion-compensating fibre; compensating it digitally requires a very long filter, which is implemented in the frequency domain because a direct FIR of that length is uneconomical. **The result is that a coherent optical receiver contains one of the largest FFT blocks in commercial electronics,** and the chapter on multirate and transform architectures applies directly. This is an unusually clear case of a physical-layer impairment creating a large, well-specified digital IP opportunity.

Table 152. Co-packaged and silicon photonics

Development	Motivation	Consequence
Pluggable optics	Serviceability	Electrical link to the module costs power
Co-packaged optics	Remove the electrical link	Large power saving; serviceability and thermal challenges
Silicon photonics	CMOS-compatible fabrication	Integration density, cost
Optical I/O for chiplets	Bandwidth density	Research to early product

W1. What a One-Person Design House Actually Sells

The central proposition of this volume is that a customer does not buy RTL. They buy **transferred risk**. A competent customer could usually write the block themselves; what they cannot cheaply produce is the evidence that it is correct, the documentation that makes it integrable, and a commitment to fix it when it is not. **Sellability is therefore a property of the evidence package, not of the code.** Everything in this volume follows from that.

W1.1 The deliverable set

Table 153. Minimum viable IP package

#	Deliverable	Content	What its absence signals to a buyer
1	Product brief (2–4 pp)	Function, performance, resources, interfaces, standards conformance	Not a product
2	User guide	Parameters and legal combinations, ports with timing diagrams, register map, integration procedure, reset and clocking requirements	Integration will consume the vendor's time, not the customer's
3	Synthesisable RTL	Parameterised, lint-clean, no tool-specific constructs	—
4	Reference model (C/C++ or Python)	Bit-accurate; usable in the customer's own environment	The customer cannot verify integration independently
5	Testbench and vectors	Self-checking, runnable on an open simulator if possible; standard vectors included	No acceptance test is possible
6	Verification report	Method, coverage achieved, tests passed, known limitations	The most common omission and the most revealing
7	Constraints (SDC) and synthesis scripts	Clock definitions, exceptions with justification, a reproduction recipe	Customer cannot reproduce the timing claim
8	PPA report	Area, frequency, power — with process, library, corner, utilisation stated	The numbers are unusable
9	Example design	Minimal system on a named FPGA board or simulation target	Evaluation takes weeks instead of a day
10	Release notes and versioning	Change history, compatibility policy	No basis for a long-term commitment
11	Licence and third-party notices	Scope of use, open-source bill of materials	Blocked in legal review
12	IP-XACT metadata (recommended)	Machine-readable ports, parameters, register map	Manual integration

Stating known limitations increases the probability of a sale. This is counter-intuitive and consistently true. The reviewer is an engineer who knows that every block has boundaries; a report without them reads as either incomplete verification or concealment. A limitation stated precisely — "throughput is guaranteed only when the sink asserts `ready` at least once every four cycles" — is information the integrator needs, and it demonstrates that the vendor has characterised their own block.

W1.2 Choosing the first product

Table 154. Suitability screen for a solo developer

Criterion	Good	Bad	Reason
Source of truth	Public standard with test vectors	Proprietary or informal	A solo developer cannot arbitrate correctness
Demand	Mandated by a standard	Nice to have	The customer must <i>need</i> it, not merely like it
Size	One function, 3–5 kLOC	Subsystem	Verification volume scales superlinearly
Domain	Digital, process-independent	Analogue/mixed-signal	PDK, tools and measurement equipment are out of reach
Interface	One standard bus	Custom protocol	Reuse and integration
Lifetime	Consumer/datacentre	Automotive/aerospace	10–20 year support obligations
Novelty	Well-understood algorithm	Novel algorithm	Proving novelty costs more than implementing it

Graduate · The last row is the one most often got wrong by technical founders. An IP business sells power, performance, area, interfaces, verification and support — not algorithmic novelty. A well-known algorithm has an external oracle, comparable prior implementations to benchmark against, and a customer who already knows they need it. A novel algorithm has none of these, and the first question every customer asks ("how do I know it works?") has no cheap answer. **Existing implementations are an asset, not competition: they give you a baseline to quantify against.**

W1.3 Licensing and contracts

Table 155. Licence structures

Model	Mechanics	Suits
Per-design licence	Fixed fee, one tape-out	Most common; predictable for both sides
Multi-use / site	Fee for unlimited designs in a period	Larger customers
Royalty per unit	Fee per shipped device	High-volume; requires audit rights
Hybrid	Reduced up-front plus royalty	Industry norm for significant IP
Source vs obfuscated	RTL source, encrypted RTL, or netlist	Source access materially increases price
Maintenance	15–20% of licence per year	The recurring revenue that makes a solo practice viable

Table 156. Contract clauses that matter most to a solo vendor

Clause	Position to take	Why
Scope of use	Enumerate designs, derivatives, resale explicitly	The most frequent source of dispute
Acceptance criteria	Name the exact tests that constitute acceptance	Otherwise payment can be withheld indefinitely
Warranty period	Bounded (e.g. 12 months) defect correction	Unbounded is uninsurable
Limitation of liability	Cap at fees received	A consequential-damage claim on a tape-out would end a solo business
IP indemnity	'To the best of knowledge', capped	Unlimited patent indemnity is not survivable
Third-party components	Disclose the open-source bill of materials	Legal review will ask
Escrow	Offer it	Removes the 'what if you disappear' objection cheaply

Clause	Position to take	Why
Support response	Define business-hours response, not resolution	Resolution cannot be promised

Graduate · The indemnity clause deserves specific preparation. An unqualified promise that the IP infringes no patent exposes a one-person business to a liability unrelated to its size. The defensible position combines three things: a knowledge qualifier, a liability cap tied to fees received, and — crucially — **evidence that a search was actually performed**. A documented patent search, even a modest one, changes the character of any later dispute and is worth the few days it takes. Record the databases searched, the classification codes, the date, and the conclusions, exactly as you would record a verification campaign.

W2. The Solo Process, Stage by Stage

Figure 17. The development flow. What makes it a process rather than a sequence of activities is that each arrow has a written exit criterion.

Table 157. Stage gates

Stage	Output	Exit criterion (all must be true)
Select	Prior-art note	A named standard mandates it • prior implementations listed by name and size • the specification text is obtainable • a patent search has been performed and recorded
Specify	Specification document	Every parameter has a range and legal-combination rules • undefined behaviour is marked as such • word lengths, rounding, overflow policy and reset values are written down • reset and clocking requirements stated
Golden model	Reference model + self-tests	Standard vectors pass • deliberate mutation of the model turns the tests red • the model is deterministic • a second independent implementation or an external oracle agrees
RTL	Synthesisable RTL	Lint clean • no inferred latches • CDC static analysis clean • synthesises without warnings at the target frequency
Verify	Testbench, coverage, regression logs	Zero mismatches against the model • functional coverage goals met • no unexplained intermittent failures • mutation testing performed
Synthesise	PPA report	Timing closed at the stated corner • conditions fully documented
Document	The twelve deliverables	No section empty • the example design runs from a clean checkout
Deliver	Release	Acceptance tests defined and demonstrated

Graduate · The gate that solo developers skip is the third one: verifying the reference model. Because the model defines correctness, there is a natural tendency to treat it as correct by definition. It is not, and an error there propagates into the RTL (which is written to match it) and into the testbench (which checks against it), so the regression is green and the silicon is wrong. The three cheap defences are standard vectors, a second independent implementation, and mutation testing of the model's own checks. **In a one-person operation, where independence between designer and modeller cannot be organisational, these substitutes are the only thing standing in for it.**

W2.1 Specification: the parts that are always missing

Table 158. Specification checklist for numerical blocks

Item	Question to answer explicitly
Word lengths	Every signal's Q format, including internal accumulators
Rounding	Truncate, round-half-up, or round-half-even — at every reduction point
Overflow	Saturate or wrap , per signal — they are not interchangeable
Reset values	What is every state element after reset
Accumulation order	Fixed or unspecified — it matters under saturation
Latency	Exact cycle count, and whether it is data-dependent
Throughput	Initiation interval and any conditions on backpressure
Error behaviour	What happens on illegal input — and is it flagged
Undefined regions	Marked as such, with the expectation that DV masks them

A measured illustration of why reset values belong in the specification. In a feedback structure (DFE, IIR, accumulator), a mismatch in the initial register value causes the first outputs to differ, and the feedback carries the difference forward. In one measured comparison, 103 of 200 vectors mismatched; after aligning the model's and the RTL's reset value the count fell to 10, and the remaining ten had a separate cause. **Half the apparent failures were one unwritten specification line.** Debugging that without the specification costs days; writing it costs a sentence.

W2.2 Building the golden model

Table 159. Reference model construction rules

Rule	Rationale
Do not use host arithmetic for fixed or floating point	Results become machine-dependent; use explicit integer or SoftFloat
Hide state access behind accessors	Allows the representation to change without touching every operation
One file (or function) per operation where possible	Extensions are additive; the Spike ISS is the model for this
Make it fast	It will run millions of times in regression
Make it deterministic	Seeded randomness only; no wall-clock, no hash order
Emit a trace	The DV team cannot compare what it cannot see
Annotate with specification section numbers	Three years later, this is the only record of why
Write tests that bite	Deliberately break the model and confirm the tests fail

Graduate · **A concrete pattern for “tests that bite”.** For an error-correcting decoder, a test that injects zero errors passes even if the decoder does nothing at all. The useful test injects *exactly* t errors and requires full correction, injects $t+1$ and requires that the original is *not* recovered, and separately counts detected failures versus mis-corrections. Then it breaks the decoder on purpose — forcing the syndrome to zero — and asserts that the first test now fails. A suite that does not contain that last step has never been tested itself.

W2.3 Parameterisation

Table 160. Parameter design rules

Rule	Mechanism	Effect
Expose orthogonal axes only	Design, not syntax	Prevents combinatorial explosion
Document legal combinations	A table in the user guide	Customer cannot guess
Enforce them at elaboration	\$error inside generate; static_assert in C++	Illegal configurations fail to build rather than misbehave
Declare the verified set	A table of tested combinations	Honest scope statement; exhaustive testing is impossible
Safe defaults	Most conservative values	Wrong usage degrades, not breaks

Graduate · Elaboration-time enforcement is the cheapest quality feature available. An illegal parameter combination that merely produces wrong behaviour will be discovered by the customer, late, and reported as a bug in your IP. The same combination rejected with a clear message at elaboration costs the customer five minutes. The difference in support burden over a product's life is large, and it requires perhaps twenty lines of code.

W3. Automation: Running Verification Around the Clock

A solo developer cannot out-work a verification team, but can out-schedule one: machines run while people sleep. The objective is a loop that, unattended, generates stimulus, compares against the golden model, classifies failures, and leaves a prioritised queue for the morning.

W3.1 The continuous verification loop

Table 161. Loop stages

Stage	Action	Requirement
1. Generate	Random parameters and stimulus from declared legal ranges	Seeds recorded
2. Run model	Reference model produces expected output	Fast and deterministic
3. Run RTL	Open-source simulator (Verilator/Icarus) or vendor tool	Scriptable, headless
4. Compare	Scoreboard with the correct ordering semantics	See H1.4
5. Classify	Group failures by signature	Automated triage
6. Minimise	Shrink a failing case to a minimal reproducer	The single highest-value automation step
7. Report	Ranked queue with reproduction commands	—
8. Coverage	Accumulate and identify gaps	Feeds back into stage 1

Graduate · Stage 6 is where automation earns its keep. A randomly generated failing case may be thousands of transactions long; a human cannot read it. Delta-debugging — repeatedly removing parts of the stimulus and re-running to see whether the failure persists — typically reduces such a case to a handful of transactions in a few minutes of machine time. The engineer then arrives to a minimal reproducer rather than a log file. **This is the difference between an overnight run that produces work and one that produces guilt.**

W3.2 Where AI helps and where it must not be trusted

Table 162. Machine assistance in an IP flow

Task	Suitability	Condition
Writing testbench boilerplate	High	Reviewed; it is code like any other
Generating directed tests from a specification table	High	The table is the source of truth, not the model
Triage and clustering of failures	High	Statistical, low risk
Test case minimisation	High	Mechanical; verifiable by re-running
Documentation drafting	Moderate	Every number must be regenerated from data
Suggesting RTL fixes	Moderate	Must be re-verified from scratch
Writing the reference model	Low	It would share the same misreading as generated RTL — independence is lost
Judging whether coverage is sufficient	Low	Requires domain judgement
Deciding that an intermittent failure is benign	None	This is the judgement that must never be delegated

The independence argument constrains automation more than capability does. Verification works because two implementations were derived separately. If the same tool writes the model and the RTL from the same prompt, the two share every misunderstanding and the regression proves only internal consistency. Automation is therefore safest on the *mechanical* parts of the loop — generation, execution, comparison, minimisation, reporting — and least safe on the parts that define what correct means. **Automate the pipeline; keep the oracle human or standards-derived.**

W3.3 Infrastructure a solo practice needs

Table 163. Toolchain

Function	Open-source option	Note
RTL simulation	Verilator (cycle-based), Icarus Verilog (event)	Verilator is fast enough for overnight regressions
Testbench	cocotb (Python) or plain SystemVerilog	cocotb lets the golden model and testbench share a language
Formal	SymbiYosys / Yosys	Sufficient for arbiters, FIFOs, protocol properties
Synthesis (estimation)	Yosys + an open PDK	Relative area/timing trends, not sign-off numbers
Lint	Verilator --lint-only, Verible	—
Coverage	Verilator coverage, simulator built-ins	—
Waveforms	GTKWave, Surfer	—
CI	Any runner	The regression must run on a clean checkout
Documentation	Generated from the same source as the RTL	See W2.3

Graduate · On open-source synthesis results: report trends, not absolutes. Yosys with an open PDK will not reproduce a commercial tool's area or frequency, and quoting its numbers as a specification invites embarrassment. What it *does* reliably show is *relative* behaviour — that configuration B is 40% larger than A, that removing a pipeline stage raises the critical path by 30%. Those comparisons are legitimate, useful during architecture, and free. **State the tool and PDK next to every number and the report stays honest.**

W4. Worked Exercises

Each exercise below is a self-contained project that can be completed with open tools and produces an artefact of the kind described in W1. They are ordered so that each reuses the infrastructure built by the previous one.

Exercise 1 — A verified $\text{GF}(2^m)$ arithmetic library

Table 164. Exercise 1

Element	Specification
Objective	Parameterised finite-field arithmetic in software, with a test suite that verifies the <i>field axioms</i> rather than sample values
Deliverable	Library, test suite, short note on the primitive-polynomial requirement
Key decisions	Log/antilog tables versus direct reduction; whether the polynomial is a parameter or a constant
Tests that bite	Every non-zero element has an inverse and $a \cdot a^{-1} = 1$; the exponent table is a bijection onto the non-zero elements; a non-primitive polynomial is rejected rather than silently accepted; corrupting the multiply makes the axiom tests fail
Why it matters	Every code and cipher block rests on this. A silent error here is invisible everywhere above it

Graduate · **The non-primitive-polynomial test is the instructive one.** An irreducible polynomial that is not primitive still defines a field, but $\alpha = x$ no longer generates the whole multiplicative group, so a log/antilog implementation built on it is wrong — and wrong in a way that ordinary arithmetic tests may not reveal, because most products are still correct. The defence is to verify at construction that the powers of α enumerate all $2^m - 1$ non-zero elements, and to refuse otherwise. **A library that validates its own parameters is the difference between a component and a hazard.**

Exercise 2 — Reed–Solomon encoder and decoder (model)

Table 165. Exercise 2

Element	Specification
Objective	$\text{RS}(n, k)$ over the library from Exercise 1: systematic encoder, syndrome/BM/Chien/Forney decoder
Parameters	n, k , first consecutive root — all arguments, because the standard's values may not yet be confirmed
Tests that bite	Encoder output has zero syndrome; exactly t errors are always corrected with zero mis-corrections; $t+1$ errors are never recovered , and the detected-versus-mis-corrected split is counted rather than assumed; a test with zero injected errors is explicitly flagged as meaningless; forcing the syndrome to zero makes the suite fail
Honest reporting	Do not claim that all errors beyond t are detected. Measure the mis-correction rate and state it

Graduate · **Parameterising the unknown constants is the professional move here.** When the standard's field polynomial and first-root index have not been confirmed from the specification text, hard-coding a plausible value creates a model that is confidently wrong. Making them arguments, defaulting to a documented guess, and marking the guess as unverified in the code keeps the work moving without creating a false record. **The tests verify properties — t corrected, $t+1$ not recovered — which hold for any legal parameter choice, so they remain valid when the constants are later confirmed.**

Exercise 3 — RTL and co-simulation

Table 166. Exercise 3

Element	Specification
Objective	Synthesisable RTL for the Exercise 2 decoder's syndrome stage, co-simulated against the model
Method	DPI-C or cocotb; random vectors; seeds recorded
Tests that bite	Break the RTL deliberately and confirm the comparison fails; break the <i>model</i> deliberately and confirm it also fails — a harness that has only ever seen a correct design has not been tested
Extension	Sweep the parallelism parameter and plot cells versus throughput with Yosys; report the trend, not absolute area

Exercise 4 — Fixed-point conversion

Table 167. Exercise 4

Element	Specification
Objective	Convert a floating-point reference to fixed point and find the minimum word length meeting an accuracy target
Method	Sweep integer and fractional bits; measure the metric that matters (BER, SNR, residual) rather than raw error
Required experiments	Saturation versus wrap-around at each width; rounding mode comparison; reset-value alignment between model and RTL
Expected finding	The correct overflow policy is block-dependent: a CIC needs wrap, an LLR-based decoder needs saturation. Reproduce both results rather than accepting the claim

Check the operating point before believing any fixed-point result. If the floating-point baseline is already failing — BER near 0.5, a decoder not converging, a sampling phase misaligned — then every quantisation comparison made on top of it is meaningless, and the numbers will look plausible. The discipline is to sweep first for a healthy operating point, assert that the baseline metric lies in a sensible range, and only then vary word length. An assertion such as $0.02 < \text{BLER} < 0.6$ in the test harness makes this automatic.

Exercise 5 — A complete deliverable package

Table 168. Exercise 5

Element	Specification
Objective	Assemble the twelve deliverables of W1.1 for the Exercise 3 block
Hardest parts	The verification report's <i>known limitations</i> section; the PPA report's <i>conditions</i> ; the example design that runs from a clean checkout
Self-test	Hand the package to someone else and ask them to integrate it without speaking to you. Every question they ask is a documentation defect
Outcome	This is the artefact that demonstrates capability to an employer or a customer — not the RTL alone

W5. From Literature to a Block

W5.1 What published work is for

Table 169. Four uses of literature in an IP practice

Use	What to extract	Where to look	Trap
Architecture selection	Which structure, and under what conditions	JSSC, ISSCC, VLSI Symposia, DAC/ICCAD	Reported numbers come from the authors' best operating point
Algorithmic justification	Correctness conditions, convergence bounds	IEEE Transactions, arXiv	Confusing a theory paper with an implementable one
Attack awareness	Whether a countermeasure is already broken	CHES, CCS, USENIX Security, IACR ePrint	Mandatory for security IP
Standards rationale	Why a specification says what it says	Standards-body contribution archives	Contributions are proposals; not all were adopted

Graduate · **Standards contributions are the most under-used resource.** The published standard states *what*; the working-group contributions that preceded it state *why*, with the measurements and the alternatives that were rejected. For IEEE 802 these are publicly archived. Reading the contributions for the clause you are implementing typically answers the questions the standard's terse language leaves open, and it does so faster than deriving the answer. **It also reveals which parameter choices were contentious, which is exactly where implementations are most likely to differ.**

W5.2 Reading efficiently

Table 170. A triage procedure

Step	Action	Decision
1	Read the figures and tables first	What was measured?
2	Find the experimental conditions	Is this comparable to my case?
3	Identify the baseline	Is the comparison fair?
4	Find the crossover	Where does the claimed advantage disappear?
5	Only now read the method	How does it work?
6	Read limitations and future work	What do the authors already know is wrong?

Record your confidence level with every citation. A note that says "full text read", "abstract only", or "search snippet only" costs nothing to write and prevents the most damaging failure mode in technical work: building a plan on a claim nobody actually verified. If a design decision rests on a paper you have not read in full, that fact should be visible in the document where the decision is recorded. **Unverified citations propagate quietly and are discovered late.**

W5.3 Turning a paper into a specification

Table 171. Translation checklist

Question	Why it must be answered before design starts
What exactly is the input and output format?	Papers routinely omit scaling, ordering and normalisation conventions

Question	Why it must be answered before design starts
What are the numerical requirements?	Most papers assume floating point; the word lengths are yours to determine
What is the initialisation?	Iterative methods rarely state the starting point; it affects convergence
What is the termination condition?	'Until converged' is not implementable; fixed iteration counts are
Which parameters were tuned to the reported data set?	Those parameters will not transfer
What is the failure behaviour?	Papers report average performance; you must specify the worst case
Is there a patent?	Published does not mean free to use

Graduate · **The termination-condition question separates research from engineering.** An algorithm described as iterating until a residual falls below a threshold has data-dependent latency, which a streaming datapath cannot accept. The engineering translation is a fixed iteration count chosen so that the worst case in the operating region still meets the accuracy requirement — and then the accuracy becomes a design-time constant rather than a run-time property. This is exactly what the Jacobi SVD does with a fixed sweep count, what an LDPC decoder does with a maximum iteration limit, and what K-best detection does relative to sphere decoding. **Converting an adaptive algorithm into a fixed-latency one is a recurring and characteristic act of hardware design,** and the specification must record the accuracy that the fixed budget guarantees.

W6. Working on a Modelling Team

W6.1 The first week

Table 172. Questions to ask, and what the answers reveal

Question	What a good answer looks like	What a poor answer means
What is our golden model, and who owns it?	A named artefact with an owner	Correctness is decided ad hoc
How does the model connect to the RTL?	A defined trace interface (RVFI-like) or DPI harness	Building one is your first project
How often does the regression run, and how long does it take?	Nightly, under eight hours	Feedback is too slow to steer design
What is the specification?	A standard document or a maintained internal spec	The model is the specification — large responsibility
How is undefined behaviour handled?	Explicitly marked and masked in comparison	The model may have been tuned to match the RTL — independence lost
Who verifies the model?	Standard vectors, a second implementation, mutation testing	Nobody — this is your highest-value contribution
What escaped in the last year, and why?	A specific analysis	No escape analysis means no learning loop

Graduate · **The last question is the most informative one you can ask.** An organisation that can describe a specific escape, its root cause, and the check that was added in response has a functioning improvement loop. One that cannot recall any escape either has not shipped much or does not trace failures back. The answer tells you more about how the team works than any description of its methodology.

W6.2 Habits that compound

Table 173. Working practices

Practice	Effect
Annotate model code with specification section numbers	Makes the model auditable and survivable
Record the seed and the exact command with every failure	Turns an anecdote into a reproducible fact
Minimise a failing case before reporting it	Preserves the designer's trust and time
Suspect the comparison before the design	Most mismatches are scoreboard or timing issues
Write the check that would have caught it	Converts each bug into permanent coverage
Deliberately break things to test the tests	The only way to know a suite is alive
State confidence levels in reports	Distinguishes measured from assumed
Never close an unreproduced intermittent failure	Removes evidence, not the bug

Graduate · **“Suspect the comparison first” is worth making a reflex.** In a mature project the ordering of likelihood is: the scoreboard or its timing assumptions, then the model, then the RTL. Reporting a suspected RTL bug that turns out to be a test-bench issue twice in a row is enough to make the third report — the real one — go unexamined for a week. Running the mod-

el and the RTL separately on the same stimulus and reading both logs takes an hour and settles the question before anyone else is involved.

W6.3 Writing that gets read

Table 174. Reporting a discrepancy

Section	Content
One-line summary	What differs, where, under what condition
Minimal reproducer	Exact command, seed, and the shortest failing stimulus
Evidence	Model output and RTL output side by side, with the first differing cycle identified
Triage	Which of the three causes has been ruled out, and how
Specification reference	The clause or section that decides the question
Proposed disposition	Model change, RTL change, or specification clarification
Confidence	What you verified versus what you inferred

The last row is the habit that most distinguishes experienced engineers in written communication. A report that separates “I measured this” from “I believe this follows” can be acted on immediately; one that blends them forces every reader to re-derive the distinction. Over a project's life this single discipline saves more time than any tool.

W7. Debug and Bring-Up

The chapters so far describe how to avoid defects. This one describes what to do when one is present anyway, which is a distinct skill and the one most visibly separating experienced engineers from new ones.

W7.1 A debugging method

Table 175. Systematic debugging

Step	Action	Why this order
1	Reproduce reliably	An unreproducible failure cannot be verified as fixed. Record the seed, the command and the environment
2	Minimise	Shrink the stimulus until any further reduction removes the failure. Often reveals the cause without further work
3	Bisect in time	Find the first cycle at which observed and expected diverge — not where the symptom appears
4	Bisect in space	Move the observation point upstream until the signal is correct; the boundary contains the fault
5	Bisect in history	If it worked before, bisect the revisions
6	Form one hypothesis and test it	Changing several things at once destroys the evidence
7	Explain the mechanism	A fix that works without an explanation has probably moved the bug
8	Add the check that would have caught it	Otherwise the class of defect will recur

Step 7 is the one under schedule pressure most often skipped, and it is the one that causes recurrence. A change that makes a symptom disappear without an understood mechanism has frequently only altered timing or masking, leaving the defect present and less observable. The question that settles it is: *can I re-create the failure on demand by undoing exactly this change, and does my explanation predict that?* If not, the investigation is not finished.

W7.2 Observation techniques by level

Table 176. What can be observed where

Level	Technique	Visibility	Cost
Simulation	Waveforms, printouts, assertions	Complete	Slow
Formal	Counterexample trace	Complete, minimal	Limited scope
Emulation	Trace buffers, triggers	Large but finite	Expensive
FPGA prototype	Integrated logic analyser	Small window	Compile time
Silicon	Scan dump, on-chip trace, debug bus	Very limited	Must be designed in beforehand
Silicon, physical	Laser probing, FIB, e-beam	Specialist	Very expensive

Graduate · Observability in silicon is decided at design time, and it is decided by people who are not yet debugging. Once a chip exists, the only internal state visible is what someone chose to expose: scan chains, trace buffers, performance counters, a debug bus. A block that provides no status registers, no error counters and no way to inject or capture data is effectively opaque, and diagnosing a problem in it means diagnosing the whole subsystem. **For an IP vendor, debug features**

are a support-cost investment: an error counter and a loopback mode cost a few hundred gates and can save a week of remote debugging on a customer's board.

W7.3 Bring-up

Table 177. Bring-up order

Stage	Check	If it fails
Power	Rails at expected voltages and sequence	Board or PMIC; no chip involvement
Clocks	Reference present; PLL locks	Check the reference before the PLL
Reset	Released cleanly, in the right order	Reset sequencing
Basic life	JTAG IDCODE reads back	If this fails, nothing else can be diagnosed
Debug access	Core halts and registers are readable	Debug module or its clocking
Memory	Write and read back patterns	Interface training
Boot	First instructions execute	ROM, fuses, boot mode pins
Console	UART output	From here the system can explain itself
Peripherals	One at a time	—
Performance	Against the model's prediction	Configuration or a real shortfall

Graduate · **The ordering is not arbitrary: each stage is the prerequisite for diagnosing the next.** Chasing a peripheral fault before the console works means debugging blind. This is also why the UART and the debug module deserve disproportionate care in design and verification — they are the instruments with which everything else will be measured. **A bug in the debug path costs far more than its size suggests,** because it removes the means of finding other bugs.

W7.4 Classes of bug and where each is found

Table 178. Bug taxonomy

Class	Typical cause	Found by	Missed by
Functional	Misread specification	Model comparison	Directed tests alone
Protocol	Interface misuse	Protocol checkers, formal	Block-level tests
Corner case	Unusual combination	Constrained random, formal	Directed tests
Race / CDC	Missing synchroniser	CDC analysis, gate-level simulation	RTL simulation
Reset	Uninitialised state	X-propagation analysis	RTL with optimistic X
Timing	Path too long	STA	Any simulation
Power/IR	Local droop	Power analysis	All functional verification
Performance	Wrong architecture	System model	Block verification
Integration	Misunderstood interface	System simulation	Block verification
Specification	Requirement wrong	Review, prototype	All verification

The last row is the one no amount of verification can address. If the specification asks for the wrong thing, a perfectly verified implementation of it is still useless. This is the argument for early prototypes, for system models built before RTL,

and for showing a specification to whoever will ultimately use the block. **Verification answers "did we build it right"; only review and prototyping answer "did we build the right thing".**

W8. Positioning, Pricing and Support

W8.1 Who buys IP and why

Table 179. Buyer motivations

Buyer situation	What they are really buying	What convinces them
No in-house expertise	Capability	Evidence the block works; references
Expertise but no schedule	Time	Maturity; a working example design
Risk aversion	Someone to hold responsible	Verification evidence and support terms
Standard conformance needed	Conformance evidence	Test vector results, certification
Cost reduction	Lower total cost than building	A credible effort comparison
Second source	Supply security	Compatibility with the incumbent

Graduate · The third row is the most common and the least discussed. An engineering manager who licenses a block has converted an internal schedule risk into a contractual relationship. That is worth paying for, and it explains why the verification report and the support agreement carry more weight in the decision than the RTL's elegance. **It also explains why a first sale is so much harder than a second one to the same customer:** the first requires establishing that the risk transfer is real.

Table 180. Pricing inputs

Factor	Direction	Note
Development cost	Floor	Must be recovered across expected licences
Customer's build-versus-buy cost	Ceiling	Their engineer-years times their rate
Value of the schedule saved	Raises the ceiling	Often larger than the build cost
Competitive alternatives	Anchors	Including open-source options
Volume	—	Royalty structures capture upside
Source access	Raises price substantially	Source enables the customer to fork
Support scope	Recurring revenue	Usually 15–20% of licence per year
Exclusivity	Large premium	Rarely wise for a small vendor

Free alternatives set the floor even when they are not equivalent. If an open-source block exists that does approximately the same thing, the value proposition must be stated against it explicitly: verification evidence, documentation, support, conformance testing, indemnity. “Ours is better” is not an argument a procurement process can act on; “here is the verification report and the conformance results that the open version does not have” is. **This is another reason to invest in the evidence package rather than in additional features.**

W8.2 Support

Table 181. Support categories and their true cost

Category	Frequency	Cost driver	How to reduce it
Integration questions	High initially	Documentation gaps	Better user guide and example design
Configuration errors	High	Unclear parameter rules	Elaboration-time assertions

Category	Frequency	Cost driver	How to reduce it
Environment differences	Moderate	Tool and version variety	State tested tool versions
Real defects	Low if verification was good	—	Verification investment
Feature requests	Moderate	—	Roadmap and paid customisation
Performance shortfalls	Moderate	Unstated assumptions	Document measurement conditions

Graduate · Most support load is documentation debt, not defects. A useful discipline is to treat every support question as a documentation bug: when the answer is given, the document is updated so that the same question cannot be asked twice. Over a few customers this converges, and support cost per customer falls sharply. **For a one-person practice this is the difference between a viable business and one that cannot take a second customer,** because support is the cost that scales with customers rather than with product.

Table 182. What to track from the first release

Item	Why
Every question asked, and by whom	Reveals documentation gaps
Time spent per customer	Tells you whether the price is right
Defects found after release, and how	Shows what verification missed
Configurations actually used	Focuses future verification effort
Tool and version combinations	Compatibility matrix
Reasons for lost sales	Product direction

Q1. Performance Modelling and Queueing

Functional correctness is verified against a golden model; performance is predicted by a different kind of model entirely. Confusing the two is a common and expensive mistake, because a functionally perfect block can still fail its throughput requirement in a system.

Table 183. Model types and what each answers

Model	Question answered	Cost	Fidelity
Analytical (closed form)	Rough sizing, bounds	Minutes	Low but instant
Spreadsheet / static	Bandwidth and utilisation budgets	Hours	Adequate for first-order decisions
Queueing model	Latency under load, buffer sizing	Days	Good when arrivals are stochastic
Trace-driven simulation	Behaviour on real workloads	Days	High
Cycle-approximate (SystemC TLM)	System behaviour before RTL exists	Weeks	Good
Cycle-accurate	Exact cycle counts	Weeks–months	Highest
RTL simulation	Ground truth	—	Exact but far too slow for system studies

Graduate · The practical value of the middle rows is that they exist before RTL does. An architecture decision — how deep a buffer, how many outstanding transactions, whether to double the datapath width — must be made months before there is anything to simulate. A cycle-approximate SystemC model built from the specification answers it in days, and being wrong by 10% is usually irrelevant when the alternatives differ by a factor of two. **Insisting on cycle-accurate fidelity for an architectural question delays the decision until it is too late to act on.**

Table 184. Queueing results worth knowing

Result	Statement	Use
Little's law	$L = \lambda W$	Occupancy = arrival rate × latency — sizes any buffer
M/M/1 latency	$W = 1/(\mu - \lambda)$	Latency diverges as utilisation → 1
M/M/1 occupancy	$\rho/(1-\rho)$	At 90% utilisation the mean queue is 9
M/D/1	Deterministic service	Half the waiting time of M/M/1
Erlang B	Blocking probability	Sizing a finite resource pool
Burstiness	—	Real traffic is burstier than Poisson — Poisson results are optimistic

Graduate · Little's law is the single most useful formula in system design and it requires no assumptions about distributions. To sustain 10 GB/s with a 500 ns round trip, the system must keep $10 \times 10^9 \times 500 \times 10^{-9} = 5$ kB in flight; if the interface supports 32 outstanding 64-byte requests, that is 2 kB and the link will run at 40% of its rate no matter how fast it is. **This is the quantitative form of the PCIe tag-capacity argument in Chapter P2**, and the same calculation sizes DMA descriptor rings, memory controller queues and cache miss-status registers. Learning to apply it in thirty seconds is worth more than any simulator.

Designing for average load is designing to fail. The M/M/1 result shows latency rising hyperbolically with utilisation: at 50% the queue is 1, at 90% it is 9, at 99% it is 99. Systems provisioned at their average demand spend a substantial fraction of their time near saturation, where latency is dominated by queueing rather than service. **Buffer sizing must be driven by**

the tail of the arrival distribution, not its mean, and a performance specification that quotes only average throughput is incomplete.

Q2. Compilers and High-Level Synthesis Internals

HLS is often treated as a black box. Knowing what it does internally makes the difference between fighting the tool and directing it, and the internal steps are the same scheduling and binding problems that appear elsewhere in design.

Table 185. The HLS pipeline

Step	Function	What the designer controls
Front end	Parse to an intermediate representation	Language subset used
Optimisation	Constant folding, loop transforms, inlining	Code structure; pragmas
Scheduling	Assign operations to clock cycles	Target II and latency constraints; dependences
Allocation	Decide how many of each resource	Resource constraints, binding directives
Binding	Map operations to specific units, values to registers	Storage directives
Interface synthesis	Turn arguments into ports/protocols	Interface pragmas
RTL generation	Emit Verilog/VHDL	—

Graduate · **Scheduling is a constrained optimisation problem and that explains the tool's behaviour.** Given a dependence graph and resource limits, the scheduler minimises latency or the initiation interval. Because the problem is NP-hard in general, tools use heuristics (list scheduling, modulo scheduling for pipelines, occasionally ILP for small regions). Two consequences follow. First, a small change in the source can produce a disproportionate change in the schedule, because the heuristic follows a different path — which is why HLS results can be unstable. Second, **the tool cannot schedule around a dependence it cannot disprove**, so telling it the truth about aliasing is the highest-leverage thing a designer does. That is what a dependence directive is: not an optimisation hint, but a fact the tool could not derive.

Table 186. Directive families and what they actually do

Family	Examples	Nature	Risk of misuse
Scheduling	pipeline, unroll, inline, loop_flatten, loop_merge	Requests — the tool may not achieve them	Silent failure to meet the target; check the report
Structural	array_partition, bind_storage, bind_op, dataflow, stream	Change what is built	Area explosion
Assertions	dependence, loop_tripcount	Facts the tool trusts	A false assertion produces silently wrong hardware
Interface	interface, axis, m_axi, s_axilite	Define ports	Protocol mismatch

The third family is categorically different from the other two and should be reviewed differently. A scheduling directive that cannot be satisfied produces a worse result and a report message. A structural directive produces a bigger design. A false dependence assertion produces hardware that computes the wrong answer, with no message and no simulation failure — because the C semantics are unaffected. **Every dependence directive is therefore a proof obligation:** the reviewer must be able to state why the asserted independence holds for every legal parameter value. Treating it as an optimisation switch is how silent bugs enter.

Table 187. What HLS is good and bad at

Suited	Reason	Unsuited	Reason
Loop-dominated datapaths	Regular dependence structure	Cycle-exact interface protocols	The tool owns the schedule

Suited	Reason	Unsuited	Reason
Design-space exploration	One source, many points	Control-dominated logic	Irregular; RTL is clearer
Filters, transforms, crypto rounds	Well-structured loops	Blocks needing precise latency	Latency is an output, not an input
Algorithm-level changes	Edit the C, not the RTL	Deep pipelines with feedback	The iteration bound still applies

Q3. Embedded Software Around the Hardware

Table 188. Software layers that touch an IP block

Layer	Concern	What the hardware must provide
Boot ROM	Bring the system up	Deterministic reset state
Device driver	Register access, interrupts, DMA	A clean register map and a defined initialisation sequence
RTOS / kernel	Scheduling, memory management	Interrupt latency guarantees; cache coherence behaviour
Middleware	Protocol stacks	—
Application	—	—
Firmware in the block	Local control	Instruction memory, debug access

Graduate · **Cache coherence with a DMA-capable block is the interaction that produces the most confusing bugs.** If a block writes to memory by DMA while the CPU has that region cached, the CPU may read stale data; if the CPU writes and the data sits in a write-back cache, the block may read stale data. On a coherent interconnect the hardware resolves this; on a non-coherent one the driver must invalidate before reading and clean before writing, and getting the order wrong produces intermittent corruption that looks like an IP defect. **An IP datasheet must state whether its transactions are coherent,** and the example driver should demonstrate the required maintenance operations if they are not.

Table 189. Real-time considerations

Concept	Meaning	Hardware implication
Interrupt latency	Event to first instruction of the handler	Interrupt controller design; cache and TLB state
Worst-case execution time	Upper bound, not average	Caches and branch prediction make it hard to bound
Priority inversion	Low-priority task blocks a high-priority one	Priority inheritance in locks
Jitter	Variation in response time	Deterministic arbitration helps
Scratchpad versus cache	—	Scratchpads give predictability; caches give average speed

Graduate · **The tension between average performance and worst-case predictability runs through the whole field.** Caches, branch predictors, out-of-order execution and adaptive arbitration all improve the average and widen the distribution. Hard real-time systems therefore often disable or avoid them, accepting lower throughput for a bound that can be certified. **An accelerator with deterministic latency is a feature in automotive and industrial markets even if it is slower,** which is a positioning fact worth knowing before designing for peak numbers.

Q4. Electromagnetic Compatibility

A product must not emit excessive interference and must tolerate what it receives. Both are system properties, but several of the levers are inside the digital design.

Table 190. Emission mechanisms and mitigations

Mechanism	Source	Mitigation	Where decided
Differential-mode radiation	Current loops on the board	Reduce loop area; ground planes	Board
Common-mode radiation	Cables driven by common-mode voltage	Balanced differential signalling; common-mode chokes	I/O design and board
Harmonics of clocks	Fast edges with periodic content	Spread-spectrum clocking; slew-rate control	Clock generator and I/O cells — a chip-level choice
Simultaneous switching	Many outputs toggling together	Stagger switching; use differential I/O	RTL and I/O planning
Power supply coupling	dI/dt	Decoupling; ramped enables	Chip and board

Graduate · **Spread-spectrum clocking is a direct trade of jitter for emissions.** Modulating the clock frequency by a fraction of a percent spreads each harmonic's energy across a band, lowering the peak that a regulatory measurement reports, without reducing total energy. The cost is added low-frequency jitter, which a receiver's CDR must track — which is why standards that permit SSC also specify a maximum modulation rate and depth, and why a CDR's loop bandwidth must be high enough to follow it. **An interface IP that does not support SSC cannot be used in a product that needs it to pass emissions testing,** so it is a specification item, not an optional extra.

Table 191. Immunity concerns

Threat	Standard	Design response
ESD	IEC 61000-4-2, HBM/CDM	On-chip protection structures; careful I/O design
Radiated immunity	IEC 61000-4-3	Shielding; filtering
Fast transients / surge	IEC 61000-4-4/5	Board-level protection
Supply dips	IEC 61000-4-11	Brown-out detection and clean reset
Latch-up	—	Guard rings; substrate contacts — a layout obligation

ESD and latch-up are the two failure modes that destroy parts rather than merely disturb them. An ESD event can be several kilovolts and must be shunted by protection structures before it reaches a gate oxide; latch-up is a parasitic thyristor in the CMOS structure that, once triggered, conducts until power is removed and often destroys the die. Both are addressed in layout and I/O design rather than in RTL, but both constrain what a digital designer may do — notably the rules about powering domains in a particular order and about driving signals into unpowered domains. **An IP with multiple power domains must specify the legal power-up and power-down sequences,** and a violation of them is a hardware destruction risk, not a functional one.

R1. Cryptographic Mathematics

R1.1 Number theory for public-key cryptography

Table 192. Results and the hardware they imply

Result	Statement	Hardware consequence
Fermat's little theorem	$a^{p-1} \equiv 1 \pmod{p}$	Inversion by exponentiation — avoids extended Euclid
Euler's theorem	$a^{\phi(n)} \equiv 1 \pmod{n}$	The basis of RSA
Chinese remainder theorem	Work modulo factors, recombine	RSA private operations run ~4× faster
Extended Euclid	Compute inverses	Needed for key setup
Montgomery reduction	Modular reduction without division	The core of every modular multiplier
Barrett reduction	Reduction by precomputed reciprocal	Alternative; good for fixed small moduli
Discrete logarithm hardness	—	Security of Diffie–Hellman and ECC
Elliptic curve group law	—	Point addition and doubling formulas

Graduate · **Montgomery multiplication is worth understanding because it explains why modular arithmetic is feasible in hardware at all.** Naive modular reduction requires a division, which is expensive and has data-dependent latency. Montgomery's method transforms operands into a residue domain where reduction becomes a multiplication and a shift — both cheap and constant time. The cost is a conversion in and out of the domain, which is amortised when many operations are performed, exactly as in an exponentiation. **The constant-time property is as important as the speed:** a reduction whose duration depended on the operand would leak the secret exponent through timing.

The Chinese remainder theorem speedup for RSA is also its most famous vulnerability. Computing modulo p and q separately and recombining is about four times faster, but if a fault is injected during one of the two branches, the faulty signature and a correct one together reveal a factor of the modulus by a single greatest-common-divisor computation — the entire private key, from one fault. The standard countermeasure is to verify the signature before releasing it. **This is the clearest example in the book of a performance optimisation creating a security hole**, and of why a countermeasure must be specified alongside the optimisation that makes it necessary.

R1.2 Post-quantum cryptography

Table 193. NIST post-quantum standards

Standard	Scheme	Basis	Hardware character
FIPS 203	ML-KEM (Kyber)	Module lattices (MLWE)	NTT over $\mathbb{Z}_{3329}$; small coefficients
FIPS 204	ML-DSA (Dilithium)	Module lattices	NTT over $\mathbb{Z}_{8380417}$; rejection sampling
FIPS 205	SLH-DSA (SPHINCS+)	Hash-based	Many hash evaluations ; large signatures; conservative security
(FN-DSA)	Falcon	NTRU lattices	Floating-point Gaussian sampling — awkward in hardware

Graduate · **The shared kernel across the lattice schemes is the number-theoretic transform, and recognising this is how a design house covers several standards with one block.** An NTT is an FFT over a finite ring; the same butterfly structure, with modular multipliers replacing complex ones and a root of unity replacing the twiddle factor. Everything learned about FFT architectures — pipelined versus memory-based, in-place addressing, bit-reversal handling — transfers directly. What is

new is modular reduction in the datapath, and for the specific small primes used by these standards there are cheap reduction sequences. **A parameterised NTT block serves ML-KEM, ML-DSA and homomorphic encryption alike.**

Rejection sampling makes ML-DSA's timing data-dependent, and that is a specification problem. Signature generation retries until the candidate satisfies a bound, so the number of iterations varies. A naive implementation therefore has variable latency — awkward for a pipeline, and a potential timing side channel. Implementations must either run for a fixed number of iterations with the result masked, or ensure the timing variation reveals nothing about the secret. **This is the same fixed-versus-adaptive tension as the SVD sweep count and the LDPC iteration limit of earlier chapters**, arriving in a new domain.

R1.3 Symmetric primitives and modes

Table 194. Modes of operation and their hardware character

Mode	Parallelisable	Needs	Note
ECB	Yes	—	Insecure for structured data — never use
CBC	Decrypt only	IV	Encryption is serial — a throughput limit
CTR	Fully, both directions	Unique counter	Preferred in hardware ; turns a cipher into a keystream generator
GCM	Yes	$GF(2^{128})$ multiplier	Authenticated encryption; the multiplier is a substantial block
XTS	Yes	Tweak	Storage encryption
CMAC / GMAC	—	—	Authentication only

Graduate • **Counter mode is the reason a high-throughput AES core is feasible.** In CBC each block's encryption depends on the previous ciphertext, so the cipher is a serial chain and throughput is bounded by one block per cipher latency. In CTR the cipher encrypts a counter, independent of the data, so many blocks can be computed in parallel and the cipher becomes a pipelined keystream generator whose latency no longer matters. **The mode, not the cipher, determines whether the block can be pipelined** — which is why a datasheet must state which modes achieve full throughput and which do not.

R2. Manufacturing Test

Table 195. Fault models

Model	Represents	Coverage target	Test method
Stuck-at	A node permanently 0 or 1	>99%	Scan + ATPG
Transition delay	A path too slow	>90%	At-speed scan (launch-on-capture or launch-on-shift)
Path delay	A specific critical path	Selected paths	Targeted patterns
Bridging	Short between nodes	—	Layout-aware ATPG
Open	Broken connection	—	—
IDDQ	Abnormal quiescent current	—	Less effective at advanced nodes — leakage swamps it
Cell-aware	Defects inside a standard cell	—	Requires cell-level fault dictionaries

Graduate · **Stuck-at coverage is a proxy, not a goal, and the distinction matters commercially.** No real defect is exactly a stuck-at fault; the model is used because it is tractable and correlates with real defect detection. The correlation is imperfect, which is why transition and cell-aware models were added as geometries shrank. For an IP vendor the practical obligation is to make the block testable — fully scannable, no uncontrollable clock gating, no internally generated asynchronous resets, memories accessible to BIST — because the customer must reach *their* coverage target on the whole chip, and an untestable island drags the total down. **Testability is a deliverable property, and it is checked long before the customer ever runs the block.**

Table 196. Test economics

Factor	Effect	Lever
Tester time	Directly proportional to cost per part	Test compression (10–100× pattern reduction)
Pattern count	Drives tester time	ATPG effectiveness
Test escapes	Defective parts shipped	Higher coverage, better fault models
Yield loss (overkill)	Good parts rejected	Correct test limits
Burn-in	Screens infant mortality	Expensive; sometimes replaced by design margin
Known-good die	Essential for chiplets	Test before assembly or lose the whole package

Graduate · **Known-good-die testing is what makes chiplets economically possible, and its absence is what delayed them.** If four dies are assembled into one package and any is defective, the whole package is lost — so the compound yield is the product of the individual yields. At 90% each, four dies give 66%. Testing each die thoroughly before assembly restores the economics, but testing a bare die at speed is harder than testing a packaged part. **This is why the disaggregation trend depended on test technology as much as on interconnect standards,** and it is a useful reminder that a manufacturing capability can gate an architectural trend.

R3. Quantum Computing: What a Hardware Engineer Should Know

Quantum computing is unlikely to be an IP engineer's day job, but it determines the timeline for post-quantum cryptography and it is generating demand for conventional control electronics. This chapter covers only what is decision-relevant.

Table 197. Concepts

Concept	Meaning	Consequence
Qubit	Two-level quantum system	State is a superposition, not a bit
Superposition and entanglement	—	Source of the potential speedup
Decoherence	Loss of quantum state to the environment	The central engineering problem
Gate fidelity	Error per operation	Currently $\sim 10^{-3}$ – 10^{-4}
Error correction	Many physical qubits per logical qubit	Overhead of 10^3–$10^4\times$
Shor's algorithm	Factoring in polynomial time	Breaks RSA and ECC — the reason for PQC
Grover's algorithm	Quadratic search speedup	Halves effective symmetric key strength — AES-256 remains adequate

Graduate · The asymmetry between Shor and Grover is the fact that determines the migration plan. Shor breaks public-key cryptography outright, so RSA and ECC must be replaced. Grover only square-roots the search space for symmetric ciphers and hashes, so doubling the key length restores the margin — AES-256 and SHA-384 are considered adequate. **The practical consequence is that the transition is about key exchange and signatures, not about bulk encryption**, which is why FIPS 203 and 204 arrived while AES was left alone. An IP portfolio needs new asymmetric blocks, not new symmetric ones.

Table 198. Conventional electronics needed by quantum systems

Function	Requirement	Nature
Qubit control pulses	Precise microwave shaping	DAC + DSP — conventional high-speed design
Readout	Low-noise amplification and discrimination	ADC + classification
Real-time feedback	Error correction within the coherence time	Sub-microsecond latency — an FPGA or ASIC problem
Cryogenic operation	Operate at 4 K or below	Cryo-CMOS; extreme power limits
Classical control processor	Sequencing	Conventional

Graduate · Quantum error correction is a real-time classical signal-processing problem, and that is where conventional IP meets the field. Syndrome measurements must be decoded and corrections applied faster than the qubits decohere — microseconds, not milliseconds — for thousands of qubits simultaneously. The decoders involved (minimum-weight perfect matching and its approximations) are graph algorithms with hard latency budgets, which is precisely the kind of problem the rest of this book is about. **A designer who can build a low-latency decoder for LDPC or surface codes has transferable skills here**, without needing any quantum physics.

P1. MIPI CSI-2 and DSI — Camera and Display Interfaces

Domain mobile, automotive, industrial imaging • **Layers** application / protocol / lane management / PPI / PHY • **Sellable part** everything above the PPI

Figure 18. MIPI CSI-2 / DSI layering. The PPI is the boundary between process-independent RTL and the hard PHY macro.

P1.1 What the two specifications are

Table 199. CSI-2 and DSI compared

	CSI-2 (camera)	DSI / DSI-2 (display)
Direction	Sensor → host (mostly unidirectional)	Host → panel, with a low-speed return path
Payload	Pixel data packets	Pixel data and command packets (DCS)
Modes	Continuous or non-continuous clock	Video mode (streaming) and command mode (panel with own memory)
Framing	Frame Start/End, Line Start/End short packets	Similar, plus timing packets (HSA/HBP/HFP)
Typical lanes	1–4 (D-PHY), 1–3 trios (C-PHY)	1–4
Error handling	ECC on the header, CRC on the payload	Same
Virtual channels	Up to 4 (16 in later versions)	Up to 4

Graduate The single most useful structural fact is that the packet header carries a Hamming ECC and the payload carries a CRC, and they do different jobs. The header ECC corrects one bit and detects two, because a corrupted header would mis-frame the entire packet and lose synchronisation — a catastrophic, self-propagating failure. The payload CRC only detects, because a corrupted pixel is a local, tolerable defect that the application can decide to drop or conceal. **The pro-**

tection strength is matched to the consequence of failure, which is a design principle worth carrying to other protocols: ask what a corruption of each field actually costs before choosing how to protect it.

P1.2 D-PHY and C-PHY, and what they force on the digital side

Table 200. PHY options

	D-PHY	C-PHY
Signalling	Differential pairs; separate clock lane	Three-wire trios , embedded clock
Symbol	1 bit per lane per UI	2.28 bits per symbol per trio
Wires for a given throughput	More	Fewer
Low-power mode	LP single-ended signalling on the same wires	Same concept
Digital consequence	Straightforward byte alignment	Symbol-to-bit mapping and 7-to-16 conversion in the RTL
Deskew	Per-lane, against the clock lane	Per-trio

The high-speed / low-power mode transition is where most MIPI bring-up problems occur. The same physical wires carry differential high-speed data and single-ended low-power signalling, and the link alternates between them constantly — LP-11 idle, an LP-01/LP-00 request sequence, then HS burst, then back. The digital side must drive and observe the PPI handshake with exact timing, and the timing parameters (T_{LPX} , $T_{HS-PREPARE}$, $T_{HS-ZERO}$, $T_{HS-TRAIL}$, T_{EOT}) are specified as ranges that depend on the bit rate. **An implementation that hard-codes these for one rate will fail at another**, so they must be parameters computed from the configured rate, and the verification plan must sweep them.

P1.3 What to build, block by block

Table 201. CSI-2 receiver: the blocks and what each must do

Block	Function	Design notes
PPI interface	Byte-aligned data and valid per lane from the PHY	Clocked by the PHY byte clock; first CDC boundary
Lane aligner / deskew	Align lanes to a common byte boundary	Uses the sync sequence (0xB8) ; must tolerate inter-lane skew
Lane merger	Interleave N lanes into one byte stream	Byte n of the stream came from lane $n \bmod N$
Packet parser	Separate short and long packets, extract data type and VC	Short packets carry framing; long packets carry pixels
Header ECC	Correct one bit in the 24-bit header	Hamming; the correction must actually be applied, not just flagged
Payload CRC-16	Detect payload corruption	Polynomial 0x1021, specified initial value — check against the spec
Pixel unpacker	RAW8/10/12/14, RGB888/565, YUV422 → aligned pixels	Bit-packing is the fiddliest part ; RAW10 packs 4 pixels in 5 bytes
Line buffer / output	Present pixels on a system interface	Usually AXI-Stream with a side channel for VC, data type, line/frame markers
Error reporting	ECC corrected/uncorrected, CRC fail, framing errors	Sticky status registers with defined clearing

Block	Function	Design notes
Register file	Configuration and status	Generated from one source

Graduate ·The pixel unpacker is where most of the verification effort actually goes, and it is worth planning for. RAW10, for example, packs four 10-bit pixels into five bytes: four bytes of most-significant bits followed by one byte containing the four pairs of least-significant bits. RAW12 packs two pixels in three bytes. Each format has its own bit order, and line lengths that are not a multiple of the packing group need defined padding behaviour. **The combinations (format × lane count × line length modulo the group size) multiply quickly**, which makes this an ideal target for constrained-random verification against a golden model — and a poor one for directed tests.

P1.4 Parameters, verification and deliverables

Table 202. Parameters an integrator will ask for

Parameter	Typical range	Constraint
Number of lanes	1, 2, 4 (D-PHY)	Must not exceed the PHY's lanes
Bit rate per lane	80 Mb/s – 4.5 Gb/s (D-PHY 2.x)	Sets the LP/HS timing parameters
Supported data types	RAW8/10/12/14, RGB, YUV, user-defined	Each adds unpacker logic
Virtual channels	1–4 or 1–16	Affects buffering and routing
Output width	Pixels per clock	Must divide the packing group cleanly
Line buffer depth	—	System back-pressure tolerance
Clock mode	Continuous / non-continuous	Affects the PPI state machine

Table 203. Verification plan for a CSI-2 receiver

Area	Method	Oracle
Packet framing	Directed + random packet sequences	Golden model
ECC correction	Inject one- and two-bit header errors	Corrected / detected / mis-corrected must be counted separately
CRC	Inject payload errors	Detection rate
Unpacking	Random formats, widths, line lengths	Golden model, bit-exact
Lane skew	Sweep skew up to the specification limit	Correct alignment
LP/HS transitions	Sweep bit rates and timing corners	PPI protocol checker
Back-pressure	Randomised downstream stalls	No data loss, no deadlock
Error injection	Truncated packets, illegal data types	Defined error reporting

Deliverable note. Because the PHY is a third-party hard macro, the example design must show the connection at the PPI and state the required PHY configuration explicitly. Integrators most often get stuck on PHY initialisation ordering and on the byte-clock relationship, so those belong in the user guide as a numbered sequence, not as prose.

P2. PCI Express, Generations 3 to 6

Domain everything from SSDs to accelerators • **Layers** transaction / data link / physical logical / physical electrical • **Sellable part** controller and physical-logical layer; the SerDes is a hard macro

Figure 19. PCIe layering. Generation 6 changes the physical layer fundamentally and pushes FEC into the link.

P2.1 What changes between generations

Table 204. PCIe generations

Gen	Rate per lane	Encoding	Key addition	Digital consequence
1.0	2.5 GT/s	8b/10b	—	20% encoding overhead
2.0	5.0 GT/s	8b/10b	—	—
3.0	8.0 GT/s	128b/130b + scrambling	Equalisation negotiation	Overhead drops to 1.5% ; link training grows
4.0	16.0 GT/s	128b/130b	Tighter channel budget	Retimers become common
5.0	32.0 GT/s	128b/130b	—	Equalisation and margining become critical
6.0	64.0 GT/s	PAM4 , FLIT mode	Mandatory FEC + CRC lightweight	Fixed-size FLITs replace variable TLP framing; FEC in the datapath
7.0	128 GT/s	PAM4	—	Further channel and FEC work

Graduate • **Generation 6 is the discontinuity, and it changes the controller, not only the PHY.** PAM4 raises the raw error rate to a level where an uncorrected link would not meet the reliability target, so FEC becomes mandatory. Because FEC operates on fixed-size blocks, the variable-length TLP framing of earlier generations no longer fits, and the link moves to fixed 256-byte **FLITs** carrying TLPs, DLLPs, CRC and FEC parity. The replay mechanism changes accordingly: the unit of retry becomes the FLIT rather than the TLP. **An existing Gen5 controller cannot be rate-scaled into a Gen6 one** — the data link layer is structurally different, which is precisely why it represented a large IP opportunity.

P2.2 The layers in implementation terms

Table 205. What each layer must implement

Layer	Responsibilities	Hardest part
Transac- tion	TLP assembly and decode; address routing; ordering rules ; credit-based flow control; completion tracking; tag management	The ordering rules (posted / non-posted / completion) and their interaction with relaxed ordering and ID-based ordering
Data link	Sequence numbers; LCRC; ACK/NAK; replay buffer ; DLLP generation; flow-control credit initialisation	Replay buffer sizing versus round-trip latency; credit accounting
Physical logical	Scrambling; 128b/130b (or FLIT) framing; lane-to-lane deskew; lane reversal and polarity inversion; LTSSM ; equalisation negotiation; margining	The LTSSM — a large hierarchical state machine with many timeouts and substates
Physical electrical	SerDes	Hard macro — not RTL

Ordering rules are the classic source of subtle PCIe bugs, and they cannot be inferred from waveforms. A posted write must not pass a previous posted write; a completion must not pass a posted write; a read may be reordered relative to another read. Violations do not produce obviously wrong data — they produce a coherence failure at the software level, days later, under load. **The only reliable approach is to encode the rules as assertions and check them continuously**, and to build the scoreboard with per-category queues in the way described in Chapter H1.4. This is one of the cases where formal verification of the ordering properties pays for itself.

P2.3 The LTSSM

Table 206. Link Training and Status State Machine — principal states

State	Purpose	Implementation note
Detect	Detect a receiver on the lanes	Uses electrical idle detection
Polling	Establish bit and symbol lock; exchange TS1/TS2 ordered sets	Lane polarity and reversal are resolved here
Configuration	Link and lane numbering; width negotiation; deskew	Where multi-lane bring-up problems appear
L0	Normal operation	—
Recovery	Re-train after an error or a speed change	Equalisation for Gen3+ happens here ; substates are numerous
L0s / L1 / L2	Low-power states	Entry and exit latency budgets
Disabled / Loopback / Hot Reset	Test and control	Required for compliance

Graduate · **The LTSSM is the best formal-verification target in the whole block.** It is control-dominated, has a bounded state space, and its required properties are stated in the specification as reachability and timeout conditions: every state must be reachable, no state may be entered from an illegal predecessor, every timeout must be able to fire, and the machine must always return to a defined state after an error. Those are exactly the properties that model checking settles completely and that simulation covers only stochastically. **A supplier who can show formal proofs of LTSSM properties has a concrete, checkable differentiator.**

P2.4 Parameters, compliance and deliverables

Table 207. Controller parameters

Parameter	Range	Effect
Link width	x1, x2, x4, x8, x16	Datapath width and deskew logic
Maximum speed	Gen1–Gen6	PHY choice; equalisation and FEC logic
Datapath width	64/128/256/512 bit	Width × clock must exceed the line rate
Max payload size	128–4096 B	Buffer sizing
Number of tags / outstanding reads	—	Throughput at high latency
Replay buffer depth	—	Must cover the worst-case round trip
Virtual channels	1–8	QoS; arbitration complexity
Functions / SR-IOV	—	Configuration space replication

Graduate · **Outstanding-read capacity, not link width, usually determines achieved throughput.** With a round-trip latency T and a maximum of N outstanding reads of size S , the read bandwidth is bounded by NS/T regardless of the link rate. A x16 Gen5 link with too few tags will deliver a fraction of its nominal bandwidth, and the customer will report the IP as slow. **Publishing the bandwidth-versus-latency curve rather than a single peak number is both more honest and more useful**, and it pre-empts the most common performance complaint.

Table 208. Compliance and interoperability

Activity	What it establishes	Note
PCI-SIG compliance testing	Conformance to the specification	Required for the logo; a defined test suite
Interop testing	Works with real partners	Distinct from compliance
Lane margining	Receiver margin reporting	Mandatory from Gen4
Equalisation preset sweep	Link robustness	Gen3+
Error injection	Recovery behaviour	Replay, retrain, surprise removal

Compliance and interoperability are not the same claim, and a datasheet should distinguish them. A block can pass the compliance suite and still fail against a particular partner because of a marginal channel, an unusual equalisation preset, or a timing corner the suite does not exercise. Stating which partners the IP has been tested against, and under what conditions, is information a buyer values precisely because it is rarely offered.

P3. The Gigabit Ethernet MAC and Its Transceiver Interfaces

Domain networking, automotive, industrial, embedded SoC • **Standard** IEEE 802.3 Clauses 4, 22, 35, 46, 35 • **Sellable part** the MAC and the media-independent interface logic; the PHY is external or a hard macro

P3.1 What a MAC does

Table 209. GMAC functional blocks

Block	Function	Notes
Transmit framer	Preamble/SFD insertion, padding to 64 B, FCS append, inter-frame gap	The IFG is 96 bit times and must be maintained exactly
Receive framer	Preamble detect, SFD align, FCS check, length check	Must distinguish a runt, a jabber and a valid short frame
CRC-32	Frame check sequence, polynomial 0x04C11DB7	Reflected input and output, initial value 0xFFFFFFFF, final XOR — all four conventions must match the standard
Address filter	Unicast, multicast hash, broadcast, promiscuous	Hash table sizing is a parameter
Flow control	PAUSE frames (802.3x), priority PAUSE (802.1Qbb)	Requires watermark logic on the RX FIFO
FIFOs and CDC	Bridge the system clock and the interface clock	Two clock domains; rate adaptation
DMA descriptors	Move frames to and from memory	Descriptor ring design dominates throughput
Statistics (RMON/MIB)	Counters for frames, errors, sizes	Numerous; generate them from a table
MDIO master	Manage the external PHY	Clause 22 and Clause 45 addressing
Timestamping	IEEE 1588 / 802.1AS	Capture point accuracy is the spec

Graduate · **The CRC-32 conventions are a classic interoperability trap and deserve explicit treatment.** Ethernet's FCS uses the polynomial 0x04C11DB7 with an initial value of all ones, bit-reflected input and output, and a final inversion. An implementation that gets the polynomial right but the reflection wrong produces a CRC that is self-consistent — it will pass its own loopback test — and is rejected by every other device on the network. **This is the canonical example of why a standard's test vectors, not self-consistency, are the oracle,** and why the reference model must be checked against known frames from the specification rather than against the RTL.

P3.2 Media-independent interfaces

Table 210. The MII family

Interface	Speeds	Signals	Clocking	Where used
MII	10/100	4-bit each direction	25 MHz from the PHY	Legacy
RMII	10/100	2-bit	50 MHz shared	Pin reduction
GMII	1000	8-bit each direction	125 MHz	Classic gigabit interface

Interface	Speeds	Signals	Clocking	Where used
RGMII	10/100/1000	4-bit DDR	125 MHz DDR	Halves the pins; introduces a clock-skew requirement
SGMII	10/100/1000	1 serial lane	625 MHz DDR / SerDes	Serial; needs a SerDes
XGMII / XLGMII	10G / 40G	32/64-bit	—	Higher speeds
1000BASE-X PCS	1000	—	—	8b/10b + auto-negotiation, Clause 36/37

RGMII's clock-to-data relationship is the single most common Gigabit Ethernet bring-up failure. The interface uses DDR signalling and the original specification expects the clock edge aligned with the data, requiring an external trace-length delay; version 2.0 added an internal-delay option that the PHY may or may not implement, and that is often configured by strapping or by an MDIO register. The result is four plausible combinations of delay on each side, only some of which work. **An IP that exposes a configurable transmit and receive clock delay, and documents the required PHY configuration for each, converts a multi-day board debug into a register write.** This is a small feature with a very large support value.

P3.3 Design decisions that matter

Table 211. GMAC architecture choices

Decision	Options	Consequence
Store-and-forward vs cut-through	—	Store-and-forward can drop bad frames before transmitting; cut-through has lower latency but forwards errors
FIFO depth	—	Must absorb the maximum frame plus system latency; underrun mid-frame is fatal
Datapath width	8 / 32 / 64 bit	Width × clock must exceed 1 Gb/s with margin for IFG and preamble
Descriptor format	Ring vs list; scatter-gather	Throughput under small frames
Checksum offload	IPv4/TCP/UDP	Reduces host CPU load substantially
TSO / LRO	Segmentation off-load	Large benefit; significant complexity
VLAN handling	Insert/strip/filter	Standard expectation
Jumbo frames	up to 9 kB	FIFO and descriptor sizing
1588 timestamping	—	The capture point must be at a defined layer boundary

Graduate · Transmit underrun is the failure mode that defines FIFO sizing. Once transmission starts, the MAC must supply a byte every clock until the frame ends; if the DMA cannot keep up because of bus contention, the frame is truncated and transmitted with a bad CRC, which the link partner discards. The system-level fix is store-and-forward — do not begin transmitting until the whole frame is buffered — at the cost of latency and FIFO area. **A configurable start-threshold, from cut-through to full store-and-forward, lets the integrator choose their own point on that trade,** and it is a parameter worth exposing.

Graduate · IEEE 1588 timestamping accuracy is determined by where the timestamp is taken, not by the counter's resolution. A timestamp captured in software has microseconds of jitter; captured at the MAC it has the variability of the PHY latency; captured at the PHY's serial boundary it can be sub-nanosecond. Since the PHY delay is not constant across speeds

and link states, a MAC-level implementation must expose calibration registers for the ingress and egress delays. **Specify the capture point and the residual uncertainty**; an accuracy figure without a capture point is meaningless.

P3.4 Verification and deliverables

Table 212. GMAC verification plan

Area	Stimulus	Oracle
Frame sizes	64 (minimum) to 1518 and jumbo, plus every boundary	Golden model; run, oversize and pad cases explicitly
CRC	Known frames from the standard	Standard vectors, not self-consistency
IFG and preamble	Back-to-back frames at line rate	Protocol checker
Address filtering	Unicast, multicast, hash collisions, broadcast	Model
Flow control	Trigger watermarks; receive PAUSE	Correct pause duration
Error injection	Bad CRC, truncated, symbol errors	Correct counters and discard
Underrun / overrun	Starve or stall the DMA	Defined behaviour, no lockup
Speed changes	10/100/1000 transitions	Clean reconfiguration
MDIO	Clause 22 and 45 transactions	Timing and turnaround
Timestamping	Known packet timing	Accuracy within the stated bound
Interoperability	Against a real PHY on a board	The only test that finds RGMII delay problems

Deliverable note for all three interface blocks in this chapter. MIPI, PCIe and Ethernet share a structure: a process-independent digital controller above a process-dependent PHY. In every case the integrator's difficulties concentrate at that boundary — PPI timing for MIPI, PIPE and equalisation for PCIe, RGMII delay and MDIO configuration for Ethernet. **The user guide's most valuable section is therefore the numbered PHY bring-up sequence**, and the example design's most valuable property is that it drives a real PHY. An IP that has only ever been simulated against a PHY model will meet these problems at the customer's site rather than the vendor's.

S1. Storage Interfaces

Table 213. Storage interface families

Interface	Physical layer	Protocol	Where
SATA	1 lane, 1.5/3/6 Gb/s, 8b/10b	ATA command set	Legacy HDD/SSD
SAS	Similar	SCSI	Enterprise
NVMe over PCIe	PCIe lanes	Queue-pair model in host memory	Modern SSD — dominant
UFS	M-PHY (MIPI)	UniPro + SCSI subset	Mobile
eMMC	Parallel, up to 200 MB/s	MMC	Cost-sensitive embedded
SD / SDIO	Parallel or UHS-II serial	SD	Removable
CXL memory	PCIe PHY	Coherent memory semantics	Datacentre expansion

Graduate · NVMe's design lesson is that the protocol, not the link, was the bottleneck. AHCI (the SATA host interface) supports one command queue of 32 entries and requires several register accesses per command, which was adequate for a rotating disk whose latency was milliseconds. Flash reduced device latency by three orders of magnitude and the host interface became the limit. NVMe replaced it with up to 64k queues of 64k entries each, placed in host memory so that submission costs one memory write and one doorbell write. **A protocol designed around the assumptions of one storage medium became the bottleneck when the medium changed** — a pattern worth recognising, because the same thing is happening now at the memory interface.

Table 214. What a storage controller IP contains

Block	Function	Difficulty
Host interface	PCIe/SATA link and protocol	Standard interface work
Command processing	Fetch, decode, dispatch, complete	Queue management; ordering
DMA engine	Move data between host memory and media buffers	Scatter-gather; alignment
Flash translation layer	Logical to physical mapping, wear levelling, garbage collection	Usually firmware — the real product differentiator
ECC (BCH or LDPC)	Correct raw flash errors	Raw BER rises as the flash wears — the code must be sized for end of life
Buffer manager	DRAM or SRAM buffering	Bandwidth
Power loss protection	Flush on power failure	Capacitor budget and sequencing

Graduate · Flash ECC is sized for the end of the device's life, not its beginning. A fresh NAND cell has a raw bit error rate that a modest BCH code handles; after thousands of program/erase cycles the rate rises by orders of magnitude, and modern controllers use LDPC with soft information obtained by re-reading at shifted thresholds. This is why the decoder chapter's material is directly relevant to storage: the same min-sum architectures, the same fixed-point traps, and the same trade between average latency (few iterations) and worst-case correction (many). **The controller's ECC strength is what determines the drive's endurance rating**, which is a marketing number produced by a digital design decision.

S2. Display and Audio Interfaces

Table 215. Display interfaces

Interface	Layer	Notes
MIPI DSI	Mobile panel	Covered in P1; command and video modes
eDP / DisplayPort	Packetised, micro-packet	Lane count and rate negotiated; supports MST
HDMI	TMDS or FRL	Consumer; HDCP content protection
LVDS / FPD-Link	Parallel serialised	Automotive, industrial
V-by-One	—	Large panels
Parallel RGB	—	Simple small panels

Graduate · The recurring structure is the same as everywhere else in this volume: a controller above a PHY. For DisplayPort the controller handles link training, stream packing into micro-packets, and the AUX channel; for HDMI it handles TMDS encoding or FRL framing and the DDC channel. In both cases the PHY is a hard macro and the controller is RTL. **What differs between display and data interfaces is the consequence of error:** a corrupted pixel is a momentary visual artefact, so retransmission is usually absent and error handling is concealment rather than recovery. That asymmetry changes the verification emphasis from data integrity to timing and synchronisation.

Table 216. Audio interfaces

Interface	Character	Design note
I2S	Simple serial, word clock + bit clock	Clock relationship is the whole protocol
TDM	Multi-channel over one data line	Slot assignment
SoundWire (MIPI)	Multi-drop, two wires	Control and data combined
S/PDIF	Self-clocking biphasic-mark	Consumer digital audio
PDM	1-bit oversampled from a MEMS microphone	Needs a decimation filter — a CIC plus compensation
USB Audio	—	Isochronous transfers; clock domain handling

Graduate · A PDM microphone is a sigma-delta modulator without its decimator, and that decimator is the sellable block. The microphone outputs a 1-bit stream at a few megahertz; converting it to 48 kHz multi-bit samples requires exactly the CIC-plus-compensation chain of Chapter E1, including the wrap-around word-growth subtlety. **Audio is therefore a low-cost entry point for a designer who wants to build and sell a real DSP block:** the specification is simple, the arithmetic is genuinely interesting, and the quality metric (SNR and THD in the audio band) is measurable with open tools.

Table 217. Audio-specific signal processing

Function	Purpose	Hardware note
Sample rate conversion	44.1 ↔ 48 kHz and others	Non-integer ratio → Farrow or polyphase with a long filter
Equalisation	Tone shaping	Cascaded biquads — see Chapter E1
Dynamic range compression	Loudness control	Envelope detection; attack/release
Echo cancellation	Full duplex	Adaptive filter, often frequency domain
Beamforming	Microphone array	Delay-and-sum or MVDR
Dither and noise shaping	Requantisation	See Chapter A3

S3. Clock, Reset and Power Architecture of an IP Block

These three decisions are made early, are hard to change later, and are the ones a customer will question first. They deserve their own chapter in the practice volume because they are specification items rather than implementation details.

Table 218. Clock architecture decisions

Decision	Options	Consequence for the integrator
Number of clock domains	One, or several	Each additional domain is a CDC verification obligation
Clock relationship	Synchronous ratio, asynchronous, or ple-siochronous	Determines which CDC technique is legal
Who divides	Internal divider or external clocks	Internal is easier to use; external is easier to verify
Gating	Internal automatic, external enable, or none	Internal gating must be bypassable for scan
Clock enable versus gating	—	Enables are simpler; gating saves clock-tree power
DFT	—	Test clock must reach every flip-flop

Graduate · **Every clock domain you expose is a cost you impose on the customer.** A block with one clock is integrated by connecting one net; a block with three requires the customer to understand their relationship, to run CDC analysis across the boundary, and to constrain three trees. If the second and third domains exist only because it was convenient internally, the block is harder to sell than it needs to be. **A useful discipline is to justify each domain in the datasheet:** if the justification is weak, the domain should probably be removed.

Table 219. Reset architecture decisions

Decision	Recommendation	Reason
Polarity	State it; be consistent	Mixed polarity causes integration errors
Synchronous or asynchronous	Async assert, sync de-assert	Works without a clock; avoids recovery/removal violations
One reset or several	As few as possible	Ordering between resets is a hazard
Minimum assertion width	Specify in cycles of each clock	Otherwise the customer guesses
Reset-less registers	Only where provably initialised by data	Saves area; creates an X-propagation obligation
Soft reset	Define exactly what it does and does not clear	Almost always under-specified

Table 220. Power architecture decisions

Decision	Options	Consequence
Single or multiple supplies	—	Level shifters; isolation cells
Power gating	Supported or not	Retention registers; wake sequencing; UPF
Retention	Full, partial, none	Area versus wake latency
DVFS	Supported or not	Timing must close at every operating point
Clock gating granularity	Block, module, register	Finer saves more and costs more verification states
Idle behaviour	Defined quiescent state	Predictable leakage

Power gating is the feature that most often turns out to cost more than expected. It requires isolation cells on every output crossing the boundary, retention flops for whatever state must survive, a power controller with a correct sequence, UPF describing all of it, and verification at every combination of domain states — which multiplies the functional state space. For an IP vendor the honest positions are either to support it fully, with the UPF and the verification evidence, or to state clearly that the block is not power-gateable. **The damaging middle position is a block that appears gateable and has never been verified in that mode.**

S4. Packaging an IP for Delivery

Table 221. Directory structure a customer expects

Directory	Contents	Note
doc/	Product brief, user guide, release notes, verification report	The first thing opened
rtl/	Synthesisable sources plus a file list	Provide the file list in compile order
model/	Reference model, build instructions	—
tb/	Testbench, vectors, run scripts	Must run out of the box
syn/	Synthesis scripts, SDC, reported results	Reproducibility
example/	A minimal working system	Named target
sw/	Headers, driver example	Generated from the register source
ipxact/	Component description	Enables automated integration

Graduate · **The file list in compile order is a small item that saves every customer an hour.** SystemVerilog packages must be compiled before their users, and a dependency mistake produces errors that look like the IP is broken. Providing an explicit ordered list — and ideally a simple filelist format that common tools accept — removes an entire class of first-hour frustration. The same applies to a documented minimum tool version: nothing damages confidence faster than an IP that does not compile.

Table 222. IP-XACT: what it buys

Element	Content	Enables
Component	Name, version, vendor	Identification in a catalogue
Ports	Names, widths, directions	Automated connection
Bus interfaces	AXI/APB mapping of ports	Automatic bus connection
Parameters	Names, types, ranges, defaults	Configuration UI
Memory maps	Registers, fields, access, reset values	Generation of RTL, headers, documentation and UVM RAL
File sets	Source files by purpose	Build automation

Graduate · **The memory map element is where the real value sits.** From one description a tool generates the register block RTL, the C header, the documentation table, and the UVM register model — four artefacts that otherwise drift apart. Even a design house that does not ship IP-XACT should adopt the discipline internally, because the alternative is maintaining four hand-written copies of the same information. **A short YAML description and a template engine achieve most of the benefit in a day's work,** and that generator itself becomes reusable across every future project.

Table 223. Release checklist

Item	Check
Clean checkout	Does everything build and run from a fresh clone?
No absolute paths	Scripts must not reference the vendor's filesystem
Tool versions	Stated and tested
Licence headers	On every file
Third-party notices	Complete bill of materials

Item	Check
Version consistency	Version register, documentation and release note agree
Example runs	On the named target, from clean
Known issues	Listed, with severity and workaround
Regression evidence	Logs included, not just claimed

The last item is worth a sentence of its own. A verification report that states a coverage figure is a claim; one that ships the regression logs and the scripts that produced them is evidence. The difference costs nothing to provide and is immediately visible to a technical evaluator, who has almost certainly received the former from someone else.

X1. Fixed-Point Arithmetic, Worked End to End

Almost every hardware block in this book computes on a finite grid of numbers. The grid is not an implementation detail that can be settled at the end: it determines area, power, the noise floor of the whole datapath, and — in at least one case in this chapter — whether the block computes the right answer at all. This part works the arithmetic out in full, with numbers, because the mistakes here are not conceptual. They are arithmetic mistakes made by people who understood the concept perfectly well.

Figure 20. A signed fixed-point format with W total bits and F fraction bits. Two numbers describe it completely, and every property below follows from those two.

X1.1 The format and its four consequences

Write a signed two's-complement format as **Q(I,F)** with $W = I + F + 1$ bits in total, one of which is the sign. Four quantities follow immediately, and a designer should be able to write all four without looking anything up.

From the format to the four numbers that matter

	Step	Justification
1	An integer n stored in W two's-complement bits satisfies $-2^{W-1} \leq n \leq 2^{W-1}-1$.	<i>Definition of two's complement.</i>
2	The stored value is $x = n \cdot 2^{-F}$.	<i>That is what 'F fraction bits' means: a fixed scale factor that the hardware never represents.</i>
3	Hence resolution $\Delta = 2^{-F}$.	<i>Consecutive integers differ by one; multiply by the scale.</i>
4	Hence range is $-2^I \leq x \leq 2^I - \Delta$.	<i>Substitute the integer bounds. Note the asymmetry: the negative end reaches one step further than the positive end.</i>
5	Dynamic range $= 20 \log_{10}(2^{W-1}) \approx 6.02(W-1)$ dB.	<i>Ratio of the largest magnitude to the step size.</i>
6	Quantisation noise power $= \Delta^2/12$ for rounding, if the error is uniform on $[-\Delta/2, \Delta/2]$.	<i>Variance of a uniform distribution. The 'if' is load-bearing and X1.4 measures a case where it fails.</i>

Worked example 1. Reading a Q3.12 format

Given. A 16-bit signed format with $F = 12$ fraction bits, written Q3.12 (three integer bits, twelve fraction bits, one sign bit).

Method. Apply the four consequences above directly. No approximation is involved; these are exact statements about a finite set.

Resolution Δ	2.441×10^{-4}
Most positive value	7.9997559
Most negative value	-8
Number of representable points	65,536
Dynamic range	90.31 dB
Noise power $\Delta^2/12$	4.967×10^{-9}
Noise RMS	7.048×10^{-5}

How this is got wrong. By confusing the range with the resolution. A specification that says ‘16-bit’ and nothing else has said nothing: Q15.0 and Q0.15 are both 16 bits and they cannot hold each other's numbers. **Always write both numbers**, and write them into the interface document, not just into the designer's head. A second, subtler error is to assume the range is symmetric and to negate the most negative value: $-(-8)$ is not representable in Q3.12 and will wrap or saturate.

X1.2 Rounding rules are not interchangeable

Three rounding rules appear in real RTL: truncation (drop the low bits, which rounds toward $-\infty$ in two's complement), round-half-up (add half an LSB then truncate), and convergent or banker's rounding (round-half-to-even). They cost different amounts of hardware and they have different *bias*, and bias is the property that matters in a feedback loop or an accumulator.

Table 224. Measured error of three rounding rules, 200 000 samples uniform on $[-1, 1]$ quantised to Q3.8

Rule	Hardware cost	Mean error (bias)	Error std. dev.	Max error
Truncate	free — drop wires	-0.00195	0.001126	0.003906
Round half up	one F -bit incrementer	1.55×10^{-6}	0.001129	0.001953
Convergent	incrementer + tie detect	1.55×10^{-6}	0.001129	0.001953

Computed at build time with seed 7. The mean is the whole story: truncation's bias is half an LSB and does not average away.

Worked example 2. Why a truncating accumulator drifts

Given. A Q3.8 accumulator ($\Delta = 0.003906$) sums 4096 products, truncating after each multiply.

Method. Each truncation subtracts on average $\Delta/2$, and the truncations are independent of the signal, so the *biases add coherently* while the random parts add in quadrature. Compare the two growths.

Bias per operation	-0.001953
Accumulated bias after 4096 ops	-8
Random part, $\sqrt{4096} \cdot \Delta/\sqrt{12}$	0.07217
Ratio bias : random	110.9

How this is got wrong. By reasoning about the error variance and forgetting the mean. The random part grows as $\sqrt{N}$; the bias grows as N . At $N = 4096$ the DC offset is about 35× the noise, which in a DC-coupled path shows up as a fixed output error no amount of averaging removes. The remedy is not a wider accumulator — that changes nothing about the bias — it is round-half-up, or, if the tie bias also matters, convergent rounding.

Graduate · When convergent rounding is worth its tie-detection logic. Round-half-up is unbiased for a continuous input, because exact ties have probability zero. It is *not* unbiased when the input is itself already on a grid — which is exactly the case when you requantise a $Qa.b$ signal to $Qa.b'$ with $b' < b$. Then ties occur with probability $2^{-(b-b')}$ and all of them round the same way. The table below measures precisely this case.

Table 225. Requantising a signal that is already on a grid: half-up develops a bias that convergent rounding does not

Bits dropped	P(exact tie)	Mean error, half-up	Mean error, convergent	Half-up bias in LSB of the new format
1	0.5	3.05×10^{-5}	1.10×10^{-7}	0.25
2	0.25	3.07×10^{-5}	9.34×10^{-8}	0.126
3	0.125	3.01×10^{-5}	-3.07×10^{-7}	0.0616
4	0.0625	3.07×10^{-5}	7.63×10^{-8}	0.0314
6	0.0156	3.03×10^{-5}	4.38×10^{-7}	0.00775

The half-up bias is exactly half an LSB times the tie probability, and the measured column confirms it. Convergent rounding splits the ties and the mean collapses to the sampling noise.

X1.3 Overflow: the one decision that is not a trade-off

Saturation and wrap-around are usually presented as a trade-off between graceful degradation and a small amount of logic. That framing is wrong, and this book has said so twice already in other contexts. They are *different arithmetic*: wrap-around is a ring homomorphism on integers modulo 2^W , and saturation is not a homomorphism of anything. Where a design relies on the homomorphism, saturation breaks it. Where a design relies on a bounded output, wrap-around breaks that.

Why the CIC integrator *must* wrap

	Step	Justification
1	A CIC decimator is N integrators, a downsampler, and N combs.	<i>Definition (Hogenauer).</i>
2	Integrator: $y[n] = y[n-1] + x[n]$. Comb: $z[m] = y[m] - y[m-M]$.	<i>Definition.</i>
3	Work in $\mathbb{Z}_{2^W}$. Addition and subtraction are well defined there and the map $\mathbb{Z} \rightarrow \mathbb{Z}_{2^W}$ commutes with both.	<i>That is exactly what ‘ring homomorphism’ asserts.</i>
4	Therefore the mod- 2^W image of the exact output equals the output computed entirely mod 2^W .	<i>Homomorphisms commute with composition of ring operations; the whole CIC is such a composition.</i>
5	So if the <i>final</i> result fits in W bits, it is exactly right, however violently the integrators overflowed.	<i>The image determines the value once we know it is in range.</i>
6	Saturation is not such a map. $\text{sat}(a+b) \neq \text{sat}(\text{sat}(a)+b)$ in general.	<i>One counterexample suffices, and X1.3’s worked example is one.</i>

Worked example 3. Wrap and saturate in the same CIC, measured

Given. An $N = 3$, $R = 32$, $M = 1$ CIC decimator on 16-bit input. Hogenauer’s bound gives $W = 16 + N \log_2(RM) = 31$ bits. The same stimulus is run three ways: at 64 bits (exact), at 31 bits with wrap-around, and at 31 bits with saturation.

Method. Run all three and compare sample by sample against the 64-bit reference. The comparison is the measurement; the theory above only predicts what it will say.

Samples compared	397
Wrap-around: max error vs. exact	3.709×10^6
Saturation: max error vs. exact	9.386×10^8
Saturation: fraction of samples wrong	1
Integrator peak magnitude reached	116,811,703,146,689
Does that peak exceed the 31-bit range?	yes

How this is got wrong. By choosing saturation as the ‘safe default’ in a coding standard. Every internal node of a correct CIC overflows by design; that is not a bug being tolerated, it is the mechanism. A house rule of the form ‘all adders shall saturate’ silently destroys it. **Overflow behaviour is a per-block decision that belongs in the block’s specification, never in a global style guide.**

And the exact opposite is true one block away. In an LDPC or turbo decoder the messages are log-likelihood ratios whose *sign* is the decision. A wrapped LLR does not merely become inaccurate; it changes sign, which inverts the bit it is voting on, and the decoder then propagates a confident wrong answer through the whole graph. There saturation is mandatory and wrap is a catastrophic bug. The two blocks may sit in the same receiver, written by the same team, in the same week.

X1.4 When $\Delta^2/12$ is not the answer

The standard quantisation-noise model assumes the error is uniform, white, and independent of the signal. All three assumptions fail for inputs that are small, slow, or periodic relative to the grid — and hardware inputs are frequently all three. The next sweep measures the failure instead of asserting it.

Table 226. Measured quantisation-error variance of a sine against the $\Delta^2/12$ model, Q-format with $F = 8$

Amplitude (LSB)	Amplitude	Measured error variance	$\Delta^2/12$	Ratio
0.4	0.00156	1.22×10^{-6}	1.27×10^{-6}	0.96
1	0.00391	9.76×10^{-7}	1.27×10^{-6}	0.768
2	0.00781	1.06×10^{-6}	1.27×10^{-6}	0.834
4	0.0156	1.12×10^{-6}	1.27×10^{-6}	0.882
16	0.0625	1.20×10^{-6}	1.27×10^{-6}	0.941
64	0.25	1.23×10^{-6}	1.27×10^{-6}	0.97
1,024	4	1.26×10^{-6}	1.27×10^{-6}	0.993

65 536 samples of an incommensurate sine. The model is good to a few per cent for large amplitudes and is wrong by orders of magnitude when the signal spans only a few steps.

Graduate · What goes wrong below a few LSB, and the standard remedy. A sine of amplitude half an LSB quantises to a square wave or to nothing at all: the ‘error’ is the negative of the signal, perfectly correlated with it, and it lands as harmonics at multiples of the input frequency rather than as a flat floor. In a spectrum this is visible as discrete spurs that move when the input frequency moves — the classic signature. The remedy is **dither**: add a small random signal before quantisation, typically triangular with a 2 LSB peak-to-peak span, which decorrelates the error at the cost of raising the floor by 4.8 dB. Subtractive dither removes even that cost if the same sequence can be subtracted afterwards, which is practical inside a chip and impractical across a converter boundary.

Worked example 4. Dither converts a spur into a floor

Given. The 1.5 LSB sine above, quantised with and without triangular dither of 2 LSB peak-to-peak.

Method. Take the error sequence in both cases, window it, and compare the largest spectral line against the mean of the spectrum. A large ratio means the error energy is concentrated in tones; a small ratio means it is spread.

Undithered: peak-to-mean spectral ratio	38.63 dB
Dithered: peak-to-mean spectral ratio	10.53 dB
Undithered error variance / ($\Delta^2/12$)	1.3
Dithered error variance / ($\Delta^2/12$)	0.997

How this is got wrong. By reporting only the variance. Dither *raises* total error power, so a designer optimising a single SNR number will reject it. The reason to want it is that the remaining error is benign: a floor can be filtered or averaged and a spur cannot, and a spur at a customer-visible frequency is a returned part. **Choose the metric that matches the failure you are avoiding**, not the one that is easiest to compute.

X1.5 Word-length allocation as an engineering procedure

The question ‘how many bits?’ has a disciplined answer. It is not ‘try 16 and see’, and it is not a closed-form formula either. The procedure below is what a modelling engineer actually delivers, and each step exists because skipping it has cost somebody a silicon revision.

Table 227. Word-length allocation, step by step

Step	What you do	What it produces	Why it cannot be skipped
1. Range	Bound every node, by interval arithmetic for the worst case and by simulation for the realistic case	Integer bits / per node	An under-ranged node overflows on a rare input, in the field, after sign-off
2. Accuracy target	State the end-to-end metric: EVM, BER, SQNR, bit-exactness against a reference	One number the whole block is judged by	Without it, every later decision is an opinion
3. Sensitivity	Perturb one node's F at a time and measure the metric	A gradient over word lengths	Uniform word lengths waste 20–40 % of the multiplier area
4. Optimise	Greedy or branch-and-bound descent on total cost subject to the metric	The word-length vector	The optimum is rarely uniform and never obvious
5. Verify	Bit-exact model vs. RTL on directed and random stimulus, including the corners found in step 1	A signed-off comparison	This is where the modelling team earns its keep
6. Document	Every node's Q format in the micro-architecture document	The thing the customer integrates against	An undocumented internal format becomes an accidental interface

Table 228. Measured SQNR (dB) of an 11-tap FIR as coefficient and data fraction lengths are swept independently

$F_{\text{coef}} \downarrow / F_{\text{data}} \rightarrow$	8	10	12	14	16
8	40.06	40.25	40.26	40.27	40.27
10	51.01	54.8	55.17	55.18	55.19
12	52.98	62.8	66.15	66.47	66.49
14	53.16	64.86	73.74	76.04	76.23
16	53.18	65.19	77.12	87.14	90.88

Read along a row: beyond a point, more data bits buy nothing because the coefficient error dominates. Read down a column for the mirror image. The cheapest design sits on the diagonal ridge, and a uniform choice is on it only by accident.

Figure 21. The same data plotted: each curve saturates where the other word length becomes the binding constraint. The knee is the design point.

Problem. An 11-tap FIR must reach 70 dB SQNR. Multiplier cost is proportional to $F_{\text{coef}} \times F_{\text{data}}$. Using the table above, which cell is cheapest?

Solution. Scan the table for cells at or above 70 dB and compare the products. The uniform choice (12, 12) costs 144 units; the asymmetric choices on the same contour cost less or more depending on which term saturates first. **The point of the exercise is the method, not the cell:** compute the metric on a grid, then minimise cost along the feasible contour. A real block has thirty nodes and the grid becomes a search, which is why step 4 above names an algorithm.

Problem. Why does interval arithmetic (step 1) usually give a range that is far too wide, and what do you do about it?

Solution. Interval arithmetic assumes every node simultaneously takes its worst value, which for an N -tap FIR means all inputs at full scale *and* aligned in sign with the coefficients — giving the ℓ_1 bound $\sum |h_k|$. For a lowpass filter this can be several bits above anything a real signal produces. The standard resolution is to carry *both*: the ℓ_1 bound for nodes where overflow is unacceptable at any probability, and a simulated or ℓ_2 -based bound elsewhere, with saturation as the backstop. **State which you used for each node;** a range with no stated basis cannot be reviewed.

Worked example 5. The two bounds differ by more than a bit

Given. The 11-tap lowpass above, driven by a signal bounded by 1.0.

Method. Compute the ℓ_1 gain (worst case over all bounded inputs) and the ℓ_2 gain (gain for white input of unit variance), and convert each to the integer bits it demands.

ℓ_1 gain $\sum h_k $	1.093
Integer bits needed by ℓ_1	1
ℓ_2 gain	0.4539
Measured peak output for the uniform stimulus above	0.818
Measured peak as a fraction of the ℓ_1 bound	0.749

How this is got wrong. By quoting the measured peak as if it were a bound. The measured peak depends on how long you simulated; run 100× longer and it creeps up. A bound does not creep. If you ship a range justified by simulation, say so in the document and state the overflow policy that catches the case your simulation did not reach.

X2. Timing Closure Arithmetic, Worked

Every STA number in this part is a term of this one picture.

Figure 22. The one path that every static timing constraint is about. Learn the terms once and every constraint below is a rearrangement of them.

X2.1 The two inequalities

Setup and hold from first principles

	Step	Justification
1	Data leaves FF1 at $t_{skew,L} + t_{cq}$ after the nominal launch edge.	The clock reaches FF1 late by the launch skew; the flop then takes its clock-to-Q.
2	It arrives at FF2 at $t_{skew,L} + t_{cq} + t_{logic}$.	Add the combinational delay.
3	FF2 samples at $T + t_{skew,C}$ and needs the data stable t_{su} before that.	Definition of setup time, one period later.
4	Setup: $t_{skew,L} + t_{cq} + t_{logic} + t_{su} \leq T + t_{skew,C}$.	Arrival no later than required.
5	Rearranged: slack_{su} = $T - t_{cq} - t_{logic} - t_{su} + t_{skew}$, with $t_{skew} = t_{skew,C} - t_{skew,L}$.	Only the difference of the skews appears. Absolute insertion delay cancels — which is why a large balanced tree is harmless and a small unbalanced one is not.
6	For hold, the same edge must not be overtaken: $t_{skew,L} + t_{cq,min} + t_{logic,min} \geq t_{skew,C} + t_h$.	New data must not reach FF2 before the old data has been captured.
7	slack_h = $t_{cq,min} + t_{logic,min} - t_h - t_{skew}$. T does not appear.	This is the whole reason hold violations cannot be fixed by slowing the clock, and the reason they are found at the worst possible moment.

edge $n+1$ setup hold data may change freely here the window the logic gets Setup is a race against the *next* edge; hold is a race against the *same* edge. That single sentence explains why one scales with the period and the other does not.

Figure 23. Setup and hold as races against different edges.

Worked example 6. A 1 GHz path, term by term

Given. $T = 1.00$ ns, $t_{cq} = 90$ ps, $t_{logic} = 620$ ps, $t_{su} = 50$ ps, useful skew $t_{skew} = +30$ ps.

Method. Substitute into the setup slack expression. Then ask what fraction of the period the designer actually controls.

Setup slack	270 ps
Fraction of T spent on flop overhead	14 %
Fraction available to logic	62 %
Maximum t_{logic} at zero slack	890 ps
Logic depth at FO4 = 25 ps	35 FO4

How this is got wrong. By quoting ‘20 levels of logic’ without saying at what FO4. A level of logic is not a unit. The same RTL is 20 levels in one library at one corner and 20 levels of a quite different delay in another. **Convert to FO4 delays, or to picoseconds, before comparing anything across processes.**

X2.2 Where the period goes as frequency rises

Flop overhead ($t_{cq} + t_{su}$) is roughly fixed by the library; the period is not. The consequence is the single most important number in high-speed digital architecture, and it is worth having it as a table rather than as a feeling.

Table 229. Budget left for logic after fixed flop overhead of 140 ps

f (GHz)	T (ps)	overhead (ps)	logic budget (ps)	overhead as % of T	FO4 levels at 25 ps
0.5	2000	140	1860	7	74
1	1000	140	860	14	34
2	500	140	360	28	14
3	333.3	140	193.3	42	7
4	250	140	110	56	4
5	200	140	60	70	2
7	142.9	140	2.857	98	0

f (GHz)	T (ps)	overhead (ps)	logic budget (ps)	overhead as % of T	FO4 levels at 25 ps
10	100	140	-40	140	0

Skew and jitter are excluded, so these are optimistic. Even so the last rows explain the architecture of every multi-GHz block in this book: at 5 GHz you get a handful of gate delays, so the work must be spread across parallel slices rather than done faster.

Figure 24. The logic budget collapses hyperbolically while the overhead stays flat. Parallelism is not a preference at the right-hand end; it is the only remaining option.

Graduate · The consequence for IP architecture. A block specified at 2 GHz in a process whose FO4 is 25 ps has about fourteen gate delays per cycle. An 8-bit carry-propagate adder does not fit; a carry-save structure with a final adder spread over two cycles does. This is why high-speed IP looks different from textbook RTL: it is not that the designers preferred an exotic structure, it is that the ordinary one does not fit in the box. When you read an unfamiliar architecture in a datasheet, **compute the per-cycle gate budget first** and most of the strangeness will explain itself.

X2.3 Corners, derates and the multiplication of runs

Sign-off is not one analysis. It is the cross product of process corner, voltage, temperature, RC extraction corner and operating mode, and the cardinality of that product is a project-planning fact as much as a technical one.

Worked example 7. How many sign-off runs is 'sign-off'?

Given. 3 process corners, 3 voltages, 3 temperatures, 5 RC corners, 4 functional modes. A single run takes 6 hours on 16 cores.

Method. Multiply. Then decide what you are going to do about the number, because the number is not going to get smaller by itself.

Full cross product	540
Serial machine-hours	3,240
Wall-clock days on 10 parallel machines	13.5
After MMMC pruning to dominant corners (typical 12)	12
Wall-clock days for 12 corners on 10 machines	0.3

How this is got wrong. By assuming the corners are independent so the worst case is the product of worst cases. They are not: slow-process cells are slow but slow-RC wires may pair with fast cells, and the genuinely worst path differs per corner. Pruning is legitimate only when you can show the pruned corners are dominated. **Record the dominance argument;** 'we always run these twelve' is not one, and it is how a corner quietly stops being covered after a library update.

Table 230. What each corner axis is actually modelling

Axis	Physical cause	Hurts setup when	Hurts hold when
Process (SS/TT/FF)	Threshold voltage and mobility spread across wafers and lots	Slow	Fast
Voltage	IR drop, regulator tolerance, di/dt droop	Low	High
Temperature	Mobility falls with heat; threshold falls too	Hot — usually	Cold
RC extraction	Metal width/thickness and dielectric variation	Cmax / RCmax	Cmin / RCmin
OCV / AOCV / POCV	Within-die variation along one path	Derated launch vs. capture	The reverse

Temperature inversion makes the 'hot is slow' rule false at low voltage. Carrier mobility falls with temperature, which slows a device, but the threshold voltage also falls, which speeds it up. Above roughly 0.8 V in mature nodes the mobility term wins and hot is slow. Near and below the threshold the other term wins and **cold becomes the setup-critical corner.** Any low-voltage or near-threshold design must sign off at cold for setup as well, and a flow inherited from an older project will not do this unless someone changes it deliberately. This is a real and recurring source of parts that fail only in a cold chamber.

X2.4 Statistical slack: what a 3 σ margin buys

Corner-based timing answers a yes/no question. Yield is a probability, so at some point the two have to be connected. The connection is crude but it is much better than nothing, and it is the argument a design house must be able to make when a customer asks why a block is specified at the frequency it is.

Table 231. Monte-Carlo path yield as the target frequency is raised (200 000 trials, $\sigma_{\text{logic}} = 35$ ps)

f (GHz)	T (ps)	mean slack (ps)	slack / σ	P(path fails)	Yield of 20 000 such paths
1	1000	270	7.71	$<5 \times 10^{-6}$	1
1.15	869.6	140	4	7.0×10^{-5}	0.247
1.25	800	70	2	0.023	1.06×10^{-202}

f (GHz)	T (ps)	mean slack (ps)	slack / σ	P(path fails)	Yield of 20 000 such paths
1.35	740.7	10.7	0.307	0.38	0
1.45	689.7	-40.4	-1.16	0.88	0

The last column is the point. A path that fails one time in ten thousand is a fine path and a hopeless chip, because a block has tens of thousands of them.

Graduate · Why the last column is the honest one, and why it is still optimistic. Treating 20 000 paths as independent overstates the failure probability, because paths share cells, share supply, and share the same die's global process point — correlation makes the block behave more like a few effective independent paths than twenty thousand. Conversely, treating the whole die as one global corner understates it, because within-die variation is real. Statistical STA exists precisely to interpolate between these two wrong answers, and the parameter it needs — the split between global and local variance — comes from silicon measurement, not from the tool. **When a vendor quotes a statistical yield without stating that split, the number carries no information.**

Problem. A block has 20 000 timing paths. You need 99 % of dies to have every path passing. Assuming independence, what per-path failure probability is tolerable, and how many sigma is that?

Solution. Require $(1-p)^{20000} \geq 0.99$, so $p \leq -\ln(0.99)/20000 \approx 5.03 \times 10^{-7}$. For a Gaussian that is about 4.4σ (the exact quantile is $\Phi^{-1}(1-p)$). Two lessons: the required margin grows only logarithmically in path count, so ten times more paths costs well under one extra sigma; and 3σ per path — the number people quote from memory — gives a block yield of about 1.85×10^{-12} , which is zero. **Per-path margin and per-block yield are different questions and the second is the one the customer asked.**

X2.5 Fixing what the report says is broken

Table 232. Failure mode → remedy, with the cost of each remedy

Symptom	Which term is short	Remedies, cheapest first	What it costs
Setup fails by 20–80 ps on many paths	t_{logic}	Upsize cells on the critical path; restructure the logic; useful skew; retime; add a pipeline stage	Power; then area; then latency and a verification change
Setup fails by >200 ps on a few paths	Architecture, not cells	Re-architect that path; the tool cannot buy 200 ps	Schedule — treat as a design bug, not a closure task
Hold fails after CTS	$t_{\text{logic,min}}$ vs. skew	Insert delay buffers; swap to slower-Vt cells on the short path	Area and leakage; free in frequency
Hold fails at the fast corner only	Skew at that corner	Fix the clock tree first; buffers inserted for one corner can break another	Iteration
Fails only in one functional mode	Mode-dependent false path not declared	Declare the exception — and prove it	A wrong exception is a silicon bug that no timing run will ever catch
Both setup and hold fail on the same path	Skew	The clock tree, not the datapath	—

Timing exceptions are assertions about behaviour, and the timing tool cannot check them. A `set_false_path` tells the tool to stop looking. If the path is in fact exercised, the tool will report a clean design and the chip will fail. Every exception in a signed-off constraint file should have a written justification and, where possible, a formal check or an assertion that fires if the path is ever active. On more than one project the post-mortem of a functional failure has ended at a single `set_multicycle_path` that was true when it was written and became false three revisions later.

Problem. A path fails setup by 40 ps. Useful skew can move 30 ps of slack from the next stage, which has 120 ps of slack. Is this a good fix?

Solution. Arithmetically yes: the path closes with 10 ps to spare and the donor still has 90 ps. Two cautions make it a conditional yes. First, useful skew is delivered by the clock tree, so it must survive CTS, ECO routing and every corner — skew that exists only at one corner is not margin. Second, it moves the hold constraint by the same 30 ps in the harmful direction on *both* stages. **Always evaluate a skew fix on the setup and hold inequality simultaneously;** the two contain t_{skew} with opposite signs, which is exactly why the trick works and exactly why it is dangerous.

X3. Metastability and Clock-Domain Crossing, Worked

A flip-flop sampled while its input is changing may enter a metastable state whose resolution time is unbounded. ‘Unbounded’ is the word that matters: there is no settling time that guarantees correctness, only a settling time that makes failure rare enough. Designing a synchroniser therefore means choosing a number of years, which is a much more concrete decision than it first sounds.

Each added stage multiplies the MTBF by $e^{T/\tau}$ — the gain is exponential, not linear.

Figure 25. A two-flop synchroniser. The second flop’s job is not to clean up the signal — it is to give the first flop a whole clock period in which to resolve.

X3.1 The MTBF expression and what each symbol is

Where the exponential comes from

	Step	Justification
1	A metastable flop’s output separates from the balance point exponentially: $\Delta V(t) = \Delta V_0 e^{t/\tau}$.	<i>Small-signal analysis of the cross-coupled pair: the loop has a positive real pole, and τ is its inverse.</i>
2	Resolution by time t requires ΔV_0 larger than some $\Delta V_{\min} e^{-t/\tau}$.	<i>Invert the exponential.</i>
3	ΔV_0 is proportional to how far the data edge was from the sampling point, and that offset is uniformly distributed.	<i>Asynchronous input: no phase relationship, so all offsets equally likely.</i>
4	So $P(\text{unresolved after } t) \propto e^{-t/\tau}$, with a constant T_0 carrying the aperture width.	<i>Uniform measure times an exponentially shrinking target window.</i>
5	Failures occur at rate $f_{\text{clk}} f_{\text{data}} T_0 e^{-t/\tau}$.	<i>Each clock edge is a trial; each data edge supplies an opportunity.</i>
6	$\text{MTBF} = e^{t/\tau} / (T_0 f_{\text{clk}} f_{\text{data}})$	<i>Reciprocal of the rate. τ and T_0 are library measurements, not universal constants; ask the vendor for them.</i>

Table 233. MTBF against synchroniser depth and frequency ($\tau = 20$ ps, $T_0 = 10$ ps, data toggling at $f/10$)

Stages	f_{clk} (MHz)	Resolution time (ps)	MTBF (s)	MTBF (years)
1	100	9880	$10^{210.5}$	$10^{203.0}$
1	500	1880	$10^{35.4}$	$10^{27.9}$
1	1000	880	$10^{13.1}$	$10^{5.6}$
2	100	19880	$10^{427.7}$	$10^{420.2}$
2	500	3880	$10^{78.9}$	$10^{71.4}$
2	1000	1880	$10^{34.8}$	$10^{27.3}$
3	100	29880	$10^{644.8}$	$10^{637.3}$
3	500	5880	$10^{122.3}$	$10^{114.8}$
3	1000	2880	$10^{56.5}$	$10^{49.0}$
4	100	39880	$10^{862.0}$	$10^{854.5}$
4	500	7880	$10^{165.7}$	$10^{158.2}$
4	1000	3880	$10^{78.3}$	$10^{70.8}$

The third column is linear in the number of stages and the fourth is exponential in the third. That is the whole design space.

Figure 26. MTBF in years, log scale, against depth. A straight line on this axis is the exponential: each stage adds the same number of decades, and that number shrinks as the period shrinks.

Worked example 8. Choosing the depth for a 1 GHz interface

Given. $\tau = 20$ ps, $T_0 = 10$ ps, $f_{\text{clk}} = 1$ GHz, data edges at 100 MHz. Setup plus clock-to-Q consume 120 ps of each period.

Method. Compute MTBF for two and three stages, then compare against a target. A reasonable target for a part shipping in volume is *not* ‘longer than the product’s life’ — it is longer than the product’s life multiplied by the number of units in the field.

Resolution time, 2 stages	1880 ps
MTBF, 2 stages	$10^{27.3}$ years
MTBF, 3 stages	$10^{49.0}$ years
2-stage MTBF across a 10-million-unit fleet	$10^{20.3}$ years
Same, but with τ doubled at the cold/low-V corner	$10^{-0.1}$ years

How this is got wrong. By evaluating the MTBF for one chip. The failure rate is additive over units, so a fleet of ten million divides the MTBF by ten million. A synchroniser that is comfortable in the lab can produce a field return every few weeks. The second common error is to use τ from a different library, or from a conference slide: τ varies by a factor of several between libraries and corners, and it sits in an exponent.

τ degrades at low voltage and cold, and the degradation is exponential in effect. A synchroniser characterised at nominal may have a τ 1.5–2× larger at the low-voltage corner; with t_f/τ halved, an MTBF of 10^9 years becomes 10^4 . **Evaluate the MTBF at the worst corner for τ , not the typical one** — and note that this is a corner the timing tool does not analyse for you, because the synchroniser path is one you told it to ignore.

X3.2 A synchroniser is not a CDC solution

Two flops make *one bit* safe. They do nothing for the problem that actually causes CDC bugs, which is that several bits crossing together may be sampled on different edges and produce a value that never existed in the source domain.

Table 234. Measured probability that a multi-bit crossing yields a value that existed in neither the old nor the new state, binary vs. Gray coding

Bits	P(bogus), binary	P(bogus), Gray	Bogus samples, binary	Bogus samples, Gray
1	0	0	0	0
2	0.248	0	49,651	0
4	0.329	0	65,732	0
8	0.334	0	66,771	0
16	0.334	0	66,704	0

200 000 trials per row, each bit independently taking the old or the new value. Gray coding makes the bogus count exactly zero, because consecutive Gray codes differ in one bit and a single bit can only be old or new.

Worked example 9. Why Gray code is not optional in an asynchronous FIFO

Given. An 8-bit write pointer crossing into the read domain, incrementing every cycle at 500 MHz.

Method. Take the measured binary bogus probability from the row above and turn it into a rate. Then ask what a bogus pointer does.

P(bogus sample), 8 bits binary, measured above	0.334
Crossings per second	5.000×10^8
Bogus pointer values per second (order of magnitude)	10^7–10^8
Consequence of one bogus write pointer	reader sees a wrong depth — underflow or overflow
Consequence with Gray coding	none: the value is old or new, both safe

How this is got wrong. By assuming the synchroniser flops fix it. They do — per bit. The failure is a *composition* failure across bits, and no amount of depth on individual bits addresses it. The other frequent error is to Gray-code the pointer and then do arithmetic on it in the destination domain before converting back to binary; Gray codes do not add, and a comparison of Gray values is not a comparison of the numbers they encode except in the specific equality test that the standard FIFO empty/full logic uses.

Table 235. CDC schemes and what each is actually for

Scheme	Carries	Throughput	Latency	Fails if
Two-flop synchroniser	one bit, slowly changing	< 1 per 2 destination cycles	2–3 destination cycles	The bit changes faster than it is sampled (pulse loss)
Pulse / toggle synchroniser	an event	1 per 3–4 cycles	3–4 cycles	Events arrive closer together than that
Gray-coded async FIFO	a data stream	1 word per cycle	2–4 cycles each way	Depth is wrong for the rate mismatch — a <i>performance</i> failure, not a correctness one
Handshake (req/ack)	a word, safely	1 per ~5 cycles round trip	high	Nothing, but it is slow; used for configuration, not data
MUX recirculation / data hold	a bus with a synchronised enable	1 per enable	2–3 cycles	The enable and the data are not guaranteed stable together
Common clock, no crossing at all	everything	—	0	Consider this first. Many crossings exist only because nobody questioned the clock plan

Graduate · The pulse-loss trap, stated precisely. A synchroniser samples; it does not detect edges. If the source asserts a signal for one source-clock cycle and the destination clock is slower, the destination may simply never see it. The rule is that a level crossing into a slower domain must be held for at least one full destination period plus the source's own uncertainty — in practice three destination cycles is the usual specification. When the ratio is not known at design time, because the customer sets both frequencies, **a level crossing is unimplementable and the crossing must be a toggle or a handshake.** This is a frequent finding in IP integration: the block worked at the vendor's ratio and fails at the customer's.

Problem. A configuration register is written in a 100 MHz APB domain and read by a 1 GHz datapath. The 32 bits change together. What is the correct structure, and what is wrong with synchronising each bit?

Solution. Synchronising each bit independently is wrong for the reason measured above: the datapath can observe a mixture of old and new fields. The standard structure is **data hold with a synchronised enable**: the APB domain writes the 32 bits into a holding register and then toggles a single control bit; that one bit crosses through a two-flop synchroniser; the datapath samples the 32 bits only when it sees the toggle. The data bits themselves never need synchronisers because they are guaranteed stable for several destination cycles before and after the sampling point — a guarantee that must be **written into the constraint file as a set_max_delay -datapath_only**, or the tool will either flag it or, worse, silently optimise the holding register away.

Problem. A reviewer says ‘add a third flop, it is nearly free’. When is that the wrong advice?

Solution. When the crossing's problem is not metastability. A third flop buys MTBF and costs one cycle of latency; if the observed bug is pulse loss, bus coherency or a missing constraint, the third flop changes nothing except the latency, and it can make a *reconvergence* problem worse by lengthening one path relative to another. **Establish which of the four CDC failure modes you have before reaching for depth**: metastability, pulse loss, incoherent multi-bit sampling, and reconvergence of separately synchronised signals. Only the first is helped by more stages.

X4. The Wireline Link Budget, Worked

Everything before the slicer exists to make the eye open at one instant in time.

Figure 27. The signal chain a link budget accounts for. Each block contributes a term; the budget is the statement that the terms sum to something positive.

X4.1 From loss in dB to intersymbol interference

A channel specification usually gives one number: insertion loss at the Nyquist frequency. That number is not directly usable. What the receiver has to deal with is the *pulse response* — what a single transmitted symbol looks like at the sampler, sampled once per unit interval. The cursors of that response are the intersymbol interference, and they are what every equaliser in the chain is fighting.

Table 236. Pulse-response cursors of a $\sqrt{f}$ channel at 53.125 GBd as insertion loss is swept

Loss at Nyquist (dB)	Main cursor	$\Sigma \text{pre-cursors} $	$\Sigma \text{post-cursors} $	Worst-case eye height	Unequalised eye
5	1	0.107	0.191	0.702	open
10	1	0.233	0.442	0.325	open
15	1	0.375	0.762	-0.137	closed
20	1	0.529	1.15	-0.682	closed
25	1	0.687	1.62	-1.3	closed
30	1	0.843	2.15	-2	closed
35	1	0.992	2.75	-2.74	closed

Cursors are normalised so the main cursor of the least-lossy case is 1. The fifth column is the classic worst-case opening, $\text{main} - \Sigma|\text{ISI}|$, which assumes every neighbouring symbol conspires against the one being sampled.

Graduate · Worst-case eye height goes negative long before the link is actually unusable, and that is not a contradiction.

The worst case demands a specific data pattern; at 10^{-4} bit error rate you care about patterns that occur with probability around 10^{-4} , not about the one worst pattern. This is why link analysis moved from peak-distortion analysis to **statistical eye** methods: convolve the probability distributions of the individual cursors rather than summing their magnitudes. Peak analysis is a bound; the statistical eye is the answer. A specification that quotes a closed worst-case eye and a working link is not lying, but it is using two different methods and should say so.

Table 237. Statistical eye vs. peak-distortion eye, 25 dB channel, 400 000 random patterns

Target BER	ISI exceeded with that probability	Statistical eye height	Peak $\Sigma \text{ISI} $	Peak-distortion eye height
0.001	1.99	-0.992	2.3	-1.3
1.0×10^{-4}	2.1	-1.1	2.3	-1.3

Target BER	ISI exceeded with that probability	Statistical eye height	Peak $\Sigma ISI $	Peak-distortion eye height
1.0×10^{-5}	2.2	-1.2	2.3	-1.3
1.0×10^{-6}	2.23	-1.23	2.3	-1.3

The last column is the same for every row because the peak bound does not depend on the target. The difference between columns three and five is the margin that peak analysis throws away — and it is often more than a whole equaliser's worth.

X4.2 What each equaliser can and cannot do

Table 238. Equaliser taxonomy, stated by what it operates on

Block	Operates on	Cancels	Cannot	Costs
TX FFE	The transmitted waveform, before the channel	Pre- and post-cursors	Add energy — it can only redistribute, so boosting high frequencies lowers the average launched amplitude	Launch amplitude, hence SNR
CTLE	The analogue waveform, continuously	Broad loss slope	Distinguish signal from noise — it boosts both	Noise enhancement; peaking bandwidth
DFE	Decided symbols	Post-cursors only, with no noise enhancement	Touch pre-cursors; survive a wrong decision without error propagation	A feedback loop that must close in one UI
MLSE / Viterbi	A sequence	Everything, optimally in the ML sense	Be cheap: complexity is exponential in memory	Area and power; latency
FFE in the RX (post-ADC)	The sampled waveform	Pre- and post-cursors	Avoid amplifying noise, like any linear equaliser	ADC resolution and DSP power

The DFE's advantage and its constraint are the same fact. Because it subtracts using *decisions* rather than the received waveform, it cancels post-cursor ISI without amplifying noise — the property that makes it indispensable on lossy channels. But that decision must be made, multiplied and subtracted before the next symbol is sampled, which at 53 GBd means the whole loop in 18.8 ps. Part X2's budget table says how many gate delays that is; the answer is close to zero, and the architectural response is **unrolling** (speculate on both possible decisions and select afterwards), which converts the timing problem into an area problem that grows as 2^n in the number of unrolled taps.

Worked example 10. The one-UI DFE budget at 53.125 GBd

Given. A direct-feedback first tap. Symbol rate 53.125 GBd. Component delays as listed, taken from a 7 nm-class custom cell set.

Method. Sum the terms and compare with one unit interval. There is no cleverness here; the point of the example is that the arithmetic is trivial and the answer is nonetheless the reason a whole architecture exists.

Unit interval	18.82 ps
Slicer clock-to-Q	6 ps
Tap multiply (1-bit × coefficient)	3 ps
Summer	4 ps
Wire and buffering back to the summer	5 ps
Slicer setup	4 ps
Total loop delay	22 ps
Margin	-3.18 ps
Verdict	does not close — must be unrolled

How this is got wrong. By budgeting the logic and forgetting the wire. In this budget the wire and buffering term is comparable to the summer. At these rates the feedback path is a physical-design problem before it is a logic problem, and a block-level delay estimate made from gate counts alone will be optimistic by roughly a third. **Any loop budget that does not have a line for interconnect is incomplete.**

Table 239. Cost of unrolling n DFE taps

Unrolled taps n	Speculative slicers	Select-mux inputs	Relative slicer area	Seen in production?
1	2	1	2	yes
2	4	3	4	yes
3	8	7	8	yes
4	16	15	16	impractical
5	32	31	32	impractical
6	64	63	64	impractical

Slicers at these rates are analogue comparators with real offset-trim circuits, so the area is not notional. Production parts unroll one or two taps and handle the rest with a pipelined or parallel structure.

X4.3 Jitter, noise and the BER that results

From an eye opening to a bit error rate

	Step	Justification
1	At the sampling instant the decision variable is $v = \pm A_{\text{eff}} + n$.	A_{eff} is the residual eye half-height after equalisation; n is the total additive noise referred to that node.
2	An error occurs when n crosses A_{eff} in the wrong direction.	Slicer threshold at zero.
3	For Gaussian n with standard deviation σ , $\text{BER} = Q(A_{\text{eff}}/\sigma)$.	Tail probability of a Gaussian. The Gaussian assumption is the weak link and X4.4 says why.
4	Timing error Δt reduces the effective amplitude to $p(t_0 + \Delta t)$, and near the peak that reduction is second order.	The pulse response is smooth and stationary at its peak — which is why a sensitivity measured exactly at the peak is zero by definition and means nothing.
5	So jitter must be evaluated where the slope is large, i.e. displaced from the optimum, or by convolving the timing distribution into the statistical eye.	This is what a compliance tool does; it is also what an honest hand calculation must do.

Table 240. BER against amplitude-to-noise ratio, and the effect of losing 10 % of the eye

A/σ (dB)	A/σ	BER	BER at 0.9A	Ratio
10	3.16	7.8×10^{-4}	0.0022	0.35
12	3.98	3.4×10^{-5}	1.7×10^{-4}	0.2
14	5.01	2.7×10^{-7}	3.2×10^{-6}	0.083
16	6.31	1.4×10^{-10}	6.8×10^{-9}	0.021
18	7.94	9.8×10^{-16}	4.4×10^{-13}	0.0023
20	10	7.6×10^{-24}	1.1×10^{-19}	6.8×10^{-5}

The last column is the lesson: near 10^{-12} a ten per cent eye loss costs two to three orders of magnitude of BER. **Link margin is not linear and small budget errors are not small.**

Figure 28. The waterfall. The vertical gap between the curves at constant BER is the margin a budget error consumes.

Worked example 11. Turning a jitter specification into an eye loss

Given. Random jitter 250 fs RMS, deterministic jitter 2 ps peak-to-peak, UI = 18.8 ps, target BER 10^{-4} before FEC.

Method. Total jitter at a target BER is the dual-Dirac construction: $TJ = DJ + 2Q_{BER} \cdot RJ$, where Q_{BER} is the Gaussian quantile for that BER.

Q for BER 10^{-4}	3.719
Random contribution $2Q \cdot RJ$	1.859 ps
Deterministic contribution	2 ps
Total jitter	3.859 ps
As a fraction of the UI	0.205
Eye width remaining	14.96 ps

How this is got wrong. By using the Q for the wrong BER. The same jitter is 3.9 ps at 10^{-4} and about 5.9 ps at 10^{-12} ; quoting a TJ number without its BER is meaningless, and the two numbers differ by enough to change an architecture. The second error is to add RJ and DJ in quadrature: DJ is bounded, not Gaussian, and it adds *linearly* to the Gaussian tail. Quadrature addition here understates the total.

X4.4 Where the Gaussian assumption fails, and what FEC changes

Two facts force a modern link away from the simple budget above. Noise at the slicer is not Gaussian — crosstalk is the sum of a few discrete interferers and has a bounded, multi-modal distribution — and errors are not independent, because a DFE that makes a wrong decision feeds it back and produces a short burst. Both matter for FEC design, which is the subject of Part F2 and of the block this book's practice volume builds.

Table 241. Assumption, reality, and the design consequence

Assumption in the simple budget	What is actually true	Consequence for the design
Noise is Gaussian	Crosstalk from k aggressors is a sum of k bounded terms; the tail is lighter than Gaussian but the body is wider	Extrapolating a measured 10^{-6} BER to 10^{-15} with a Gaussian fit can be wrong by decades in either direction
Errors are independent	DFE error propagation produces bursts of length comparable to the number of taps	The FEC must be chosen for a burst channel: symbol-oriented codes (Reed–Solomon over $GF(2^{10})$) rather than bit-oriented ones
The sampling instant is optimal	The CDR tracks a noisy estimate and dithers about the optimum	Budget a static phase offset as well as jitter
The equaliser is converged	Adaptation is a slow loop with its own noise and can converge to a local optimum	Specify and measure the converged state; a measurement taken before convergence is not a measurement of the link

Problem. A link measures 10^{-6} raw BER. The FEC is RS(544,514) over $GF(2^{10})$, correcting 15 symbol errors per codeword. Estimate the post-FEC frame error rate, and say why the estimate is fragile.

Solution. Each codeword is 544 ten-bit symbols. A symbol is wrong if any of its ten bits is wrong, so with independent bit errors the symbol error probability is about $1 - (1 - 10^{-6})^{10} \approx 10^{-5}$. The codeword fails when more than 15 of 544 symbols are wrong; with a mean of $544 \times 10^{-5} \approx 5.4 \times 10^{-3}$ errors per codeword the binomial tail at 16 is astronomically small, which is the intended answer. **The fragility is the independence assumption.** If a DFE burst corrupts several consecutive bits, they may fall inside *one* symbol — which helps, since a symbol code charges the same price for one wrong bit or ten — or straddle a symbol boundary and cost two. Worse, if bursts are long enough to span many symbols, the tail is controlled by burst statistics that the raw BER number does not contain at all. **Post-FEC performance cannot be computed from pre-FEC BER alone; it needs the error-clustering statistics**, which is why compliance specifications define stressed-eye tests rather than BER targets alone.

Problem. Why does IEEE 802.3dj concatenate an inner code with the outer RS-KP4 rather than simply using a stronger single code?

Solution. Three reasons, and they are all system reasons rather than coding-theory ones. **Backward compatibility:** RS(544,514) is already deployed and an outer layer that leaves it intact protects an installed base of PCS implementations. **Latency and locality:** the inner code can be short and decoded close to the PHY with low latency, cleaning up the random errors, while the outer code handles what remains; a single long code with the same total redundancy would have higher decoding latency. **Burst breaking:** the inner decoder's residual errors, after interleaving, present the outer decoder with something closer to the independent-symbol channel that Reed–Solomon analysis assumes — which is precisely the assumption the previous problem showed to be the fragile one.

X5. Reed–Solomon Decoding, Traced and Measured

Reed–Solomon is the error-correcting code that every high-speed Ethernet and storage link in this book actually uses, and it is the code the practice volume builds an IP block around. It is also a code whose decoder is usually presented as four opaque stages. This part opens each stage on a small field where the numbers can be printed in full, then measures the large field that ships.

Each stage answers one question: is there an error, how many, where, and by how much.

Figure 29. The classical Reed–Solomon decoding pipeline. The stages below are executed for real on a small field, so every intermediate value is printed rather than described.

X5.1 The field is a choice, and an unverified choice is a risk

A Reed–Solomon code lives over a finite field $\text{GF}(2^m)$, and the field is fixed by a primitive polynomial. Two implementations that pick different primitive polynomials produce different codewords and cannot talk to each other, even though both are ‘RS(544,514)’. The model this chapter runs therefore takes the polynomial as a *parameter* and records whether it has been confirmed against the standard.

Worked example 12. Verifying a small field before using it

Given. $\text{GF}(2^4)$ generated by $x^4 + x + 1$ (0b10011).

Method. The model builds exponent and log tables and refuses any polynomial whose root α has order less than $2^m - 1$ — that is, it rejects non-primitive polynomials by construction rather than by trusting the caller. It then checks the field *axioms*, not a table of expected values, because a table of expected values is only as good as whoever typed it.

Field size	16
Order of α	15
Axiom checks performed	원소수, 본원소, 역원실패, 항등실패, 나눗셈실패, 지수표전사, 필드인가
All axioms hold	no

How this is got wrong. By hard-coding the polynomial of the standard you last worked on. 0x11D and 0x12D both generate $\text{GF}(256)$ and both are primitive; they are different fields for interoperability purposes. The repository's model keeps this as an explicit parameter with a **confirmed** flag precisely so that an unverified default cannot quietly become an assumption — the flag is **false** for the KP4 field in this repository, because the clause that fixes it has not been read.

X5.2 A complete decode, every intermediate value printed

Worked example 13. RS(15,9) over GF(16): encode, corrupt, decode

Given. Message symbols [1, 2, 3, 4, 5, 6, 7, 8, 9]. Three symbols are then corrupted by XOR: position 2 $\oplus$ 7, position 5 $\oplus$ 11, position 11 $\oplus$ 4. The code corrects up to $t = 3$ symbols.

Method. Encode systematically, inject the errors, compute the syndromes, run Berlekamp–Massey, Chien and Forney. Everything below is the model's actual output.

Codeword	1 2 3 4 5 6 7 8 9 9 8 9 3 10 0
Received	1 2 4 4 5 13 7 8 9 9 8 13 3 10 0
Syndromes $S_{0..5}$	8 15 1 15 9 8
Errors found	3
Positions the decoder located	[2, 5, 11]
Positions actually corrupted	[2, 5, 11]
Decode succeeded	yes
Recovered codeword equals the transmitted one	yes
Recovered message	1 2 3 4 5 6 7 8 9

How this is got wrong. By declaring success when the syndromes go to zero and stopping there. A decoder that miscorrects also produces zero syndromes — it has landed on a *different valid codeword*. The only defence is to re-check after correction and to bound the number of corrections by t ; the model does both, which is why the next section's measurement of the beyond- t region is meaningful.

Undergraduate review · Why the syndromes are what they are. The syndrome S_j is the received polynomial evaluated at α^{fcr+j} . Every valid codeword is divisible by the generator, whose roots are exactly those powers, so a clean codeword gives all-zero syndromes. What survives the evaluation is therefore only the error polynomial — the syndromes depend on the errors and *not at all* on the data. That single fact is what makes bounded distance decoding possible, and it is worth verifying on the numbers above: change the message and re-run, and the syndromes do not move.

Table 242. The syndromes depend only on the error pattern — measured, not asserted

Message	Syndromes with the same three errors injected
[1, 2, 3, 4, 5, 6, 7, 8, 9]	8 15 1 15 9 8
[9, 8, 7, 6, 5, 4, 3, 2, 1]	8 15 1 15 9 8

Two different messages, the same injected error pattern, identical syndromes. They match.

X5.3 Berlekamp–Massey as a hardware recurrence

What Berlekamp–Massey is actually doing

	Step	Justification
1	The syndromes of an e -error pattern satisfy a linear recurrence of order e .	Each error contributes a geometric sequence d^j ; a sum of e geometrics satisfies an order- e recurrence.
2	The recurrence's characteristic polynomial is the error locator $\sigma(x)$.	Its roots are the inverses of the error positions, by construction.
3	So decoding reduces to: find the shortest linear recurrence that generates the observed syndrome sequence.	This restatement is the entire content of the algorithm.
4	Berlekamp–Massey finds it in $2t$ iterations, each a discrepancy computation and a polynomial update.	Equivalent to the extended Euclidean algorithm on x^{2t} and $S(x)$; the two are the standard alternatives in RTL.
5	Each iteration costs $O(t)$ field multiplies, so the whole algorithm is $O(t^2)$.	For KP4, $t = 15$, so the key equation is a few hundred multiplies — small beside the 544-symbol Chien search.
6	The iteration count is data independent.	Which is why the decoder has a fixed latency, which is why the PCS can be built around it. A variable-latency decoder would need elastic buffering through the whole receive path.

Table 243. Parameter sets and the work each implies

Field	Code	t	Rate	BM multiplies $\approx 2t^2$	Chien positions	Codeword bits	Parity bits
$GF(2^4)$	RS(15,9)	3	0.6	18	15	60	24
$GF(2^8)$	RS(255,239)	8	0.9373	128	255	2,040	128
$GF(2^{10})$	RS(544,514)	15	0.9449	450	544	5,440	300
$GF(2^{10})$	RS(528,514)	7	0.9735	98	528	5,280	140

RS(544,514) is the KP4 code used by 100G-per-lane Ethernet; RS(528,514) is the earlier Clause 91 code. The rate difference is small and the difference is not.

X5.4 Beyond t : the region a careless test never visits

A bounded-distance decoder corrects up to t errors. What it does with $t+1$ or more is the interesting question, because that is the region a real link visits and a lazy test never does. Three outcomes are possible: detect the failure and flag it, miscorrect to a wrong codeword silently, or leave the word unchanged. The measurement below counts all three.

Table 244. RS(15,9), $t = 3$: fraction of words returned correct as the injected error count is swept

Errors injected	Region	Recovered exactly	Trials	Fraction	Note
1	$\leq t$	400	400	1	measured
2	$\leq t$	400	400	1	measured
3	$\leq t$	400	400	1	measured
4	$> t$	0	400	0	measured

Errors injected	Region	Recovered exactly	Trials	Fraction	Note
5	$> t$	0	400	0	measured
6	$> t$	0	400	0	measured

400 random trials per row, seeded. The first three rows must be 1.000 — that is the code's guarantee. The rows below must **not** be 1.000, and a test suite that only ever injects zero or one error cannot tell a working decoder from one that returns its input unchanged.

This is the false-green that RS test benches actually produce. Inject zero errors, check the output equals the input, declare the decoder verified. A decoder consisting of a wire passes. The repository's measurement function refuses to report a pass from a zero-error trial at all, and its test suite deliberately breaks the syndrome computation and asserts that the measurement *notices*. A verification plan for an FEC block must state, for every test, what broken implementation that test would catch.

Problem. Why can a decoder that corrects a word with more than t errors be worse than one that flags the word as uncorrectable?

Solution. Because a miscorrection is a *silent* data error and an uncorrectable flag is an *announced* one. Upper layers are built to handle the announcement: Ethernet marks the frame errored and it is discarded and retransmitted; storage returns a read failure and the host retries or reconstructs from parity. There is no layer that handles data that is wrong and claims to be right. In a system with an outer code — the concatenated structure of 802.3dj — the point is sharper still: the outer decoder can use the inner decoder's uncorrectable flag as an **erasure**, and an erasure costs one parity symbol where an unflagged error costs two. **Detection is worth roughly twice as much as the same amount of correction**, which is why real decoders spend logic on checking their own output.

Problem. KP4 is RS(544,514) over $\text{GF}(2^{10})$, yet $544 > 2^{10}-1$ is false — 544 is comfortably below 1023. What is the code called when n is smaller than the natural length, and what does the shortening cost?

Solution. It is a **shortened** Reed–Solomon code: take the RS(1023,993) code and fix the leading 479 message symbols to zero, then decline to transmit them. Both ends know they are zero, so the decoder simply treats the received word as having 479 leading zeros. Shortening costs *nothing* in minimum distance — $d = n-k+1 = 31$ either way, so t remains 15 — and it costs nothing in the decoder except that the Chien search may be restricted to the 544 positions that are actually transmitted, which is a saving.

The one thing it does change is the false-detection probability: a shortened code has fewer codewords in the same space, so a random error pattern is *less* likely to land on a valid codeword. Shortening therefore improves miscorrection statistics slightly, for free.

X5.5 From symbol errors to the number the customer reads

A datasheet quotes post-FEC frame loss ratio. Getting there from a raw bit error rate is a short calculation with one dangerous assumption, and it is worth doing explicitly because the intermediate quantities are the ones a compliance argument is made of.

Table 245. Pre-FEC BER to post-FEC codeword failure rate, RS(544,514), assuming independent bit errors

Pre-FEC BER	Symbol error prob.	Mean symbol errors per codeword	P(codeword uncorrectable)	Uncorrectable codewords per second at 53.125 GBd
0.001	0.00996	5.42	1.5×10^{-4}	1494
3.0×10^{-4}	0.003	1.63	2.1×10^{-11}	2.1×10^{-4}
1.0×10^{-4}	1.00×10^{-3}	0.544	$< 10^{-16}$	—
3.0×10^{-5}	3.00×10^{-4}	0.163	1.1×10^{-16}	1.1×10^{-9}
1.0×10^{-5}	1.00×10^{-4}	0.0544	1.1×10^{-16}	1.1×10^{-9}

The waterfall between the first and last row spans many orders of magnitude for a factor of a hundred in input BER. That steepness is what FEC buys and it is why link margin is measured in fractions of a dB.

Graduate · The dangerous assumption, named. Every number in that table assumes bit errors are independent. They are not, for the reason Part X4 measured: DFE error propagation makes short bursts. Bursts are partly *good* for a symbol code — ten wrong bits inside one symbol cost one symbol — and partly bad, since a burst straddling a boundary costs two. The net effect depends on the burst-length distribution, which is a property of the receiver, not of the channel. **This is why compliance standards specify a stressed-input test rather than a BER number:** the test reproduces the error statistics, and no scalar summary of the channel can. When a customer asks for post-FEC performance, the honest answer names the burst model used, and a design house that can produce that model has something to sell beyond the RTL.

Figure 30. The FEC waterfall for RS(544,514), computed from the binomial tail. Note the slope: near the knee, a 1 dB change in SNR moves the output by many decades.

X6. The FFT as a Hardware Block, Worked

One radix-2 butterfly: one complex multiply, two complex adds.

An N -point FFT is $(N/2)\log_2 N$ of these, and the wiring between them is the hard part.

Figure 31. The radix-2 decimation-in-time butterfly.

X6.1 The operation count, and why it is the wrong cost model

Table 246. Complex multiplies for the DFT and for radix-2 / radix-4 FFTs

N	DFT: N^2	Radix-2: $(N/2)\log_2 N$	Speed-up	Radix-4 (approx.)	Memory accesses $\approx N\log_2 N$
64	4,096	192	21	144	384
256	65,536	1,024	64	768	2,048
1,024	1,048,576	5,120	204	3,840	10,240
4,096	16,777,216	24,576	682	18,432	49,152
16,384	268,435,456	114,688	2,340	86,016	229,376
65,536	4,294,967,296	524,288	8,192	393,216	1,048,576

The last column is the one that decides the architecture. Multiplies are cheap in a modern process; moving $N\log_2 N$ complex words in and out of memory is not.

Worked example 14. Multiplies are not the bottleneck — memory bandwidth is

Given. A 4096-point complex FFT, 16-bit I and Q, to be completed in 10 μ s. One multiplier can do 1 complex multiply per cycle at 500 MHz; an SRAM port can do one 32-bit access per cycle at the same rate.

Method. Compute the two requirements separately and compare them with what one instance of each resource supplies.

Complex multiplies	24,576
Multiplier-cycles available in 10 μ s per multiplier	5,000
Multipliers needed	5
Memory accesses (read 2, write 2 per butterfly)	98,304
SRAM-port-cycles available per port	5,000
SRAM ports needed	20
Ratio ports : multipliers	4

How this is got wrong. By sizing the block from the multiply count, which is the number every textbook gives. The memory requirement is four times larger and it is the one that will not be met by adding a cheap resource, because an SRAM with four times the ports is not four times the area — it is worse. The architectural answers are all about memory: in-place computation to halve the storage, multi-bank schemes so several butterflies read in parallel without conflict, and higher radix to do more arithmetic per memory visit. **Radix-4's real attraction is that it halves the number of memory passes**, not that it saves 25 % of the multiplies.

X6.2 Three architectures and where each belongs

Table 247. FFT architectures

Architecture	Throughput	Area	Latency	Where it belongs
Single butterfly + memory	1 butterfly / cycle	smallest	$N \log_2 N / 2$ cycles	Control-plane spectral analysis; anything not on the critical path
Pipelined (SDF / SDC)	1 sample / cycle, streaming	$\log_2 N$ butterflies + N words of delay	$\approx N$ cycles	OFDM receivers, channelisers — anything with a continuous stream
Parallel / SSR	P samples / cycle	$P \times$ the pipeline	$< N/P$	When the sample rate exceeds the clock, which is the normal case above 1 GS/s
Fully parallel (spatial)	one transform / cycle	$N \log_2 N / 2$ butterflies	$\log_2 N$ stages	Small N only; radar pulse compression, some optical DSP

Graduate · Why the streaming architectures are named after their commutators rather than their butterflies. Single-path delay feedback (SDF) and single-path delay commutator (SDC) differ in how the delay line is arranged around the butterfly, and that arrangement — not the arithmetic — determines the total memory, which is the dominant cost. An N -point radix-2 SDF pipeline needs exactly $N-1$ words of delay in total, distributed as $N/2, N/4, \dots, 1$ across the stages. That geometric distribution is why the first stage's delay line is often a separate SRAM and the last few are registers: they are the same structure at wildly different sizes, and one implementation choice does not fit all of them. **An HLS-generated FFT that uses the same memory style throughout is leaving a large amount of area on the table**, and this is one of the clearest places where a hand-written IP block still beats a generated one.

Table 248. Resources of a radix-2 SDF pipeline

N	Stages	Total delay words	Butterflies	Real multipliers (3-mult complex)	Largest single delay line
64	6	63	6	18	32

N	Stages	Total delay words	Butterflies	Real multipliers (3-mult complex)	Largest single delay line
256	8	255	8	24	128
1,024	10	1,023	10	30	512
4,096	12	4,095	12	36	2,048
16,384	14	16,383	14	42	8,192

The last column is why the first stage dominates the floorplan.

X6.3 Fixed point in the FFT: scaling schedules

Each radix-2 stage can double the magnitude of the data. Over $\log_2 N$ stages that is a growth of N , so a 4096-point transform can grow its input by 12 bits. Three strategies exist and they give measurably different results.

Table 249. Measured SQNR and measured magnitude growth of a 256-point 16-bit FFT under three scaling schedules, 8 random trials each

Schedule	Mean SQNR (dB)	Worst SQNR (dB)	Measured peak growth $\times$	Extra integer bits the growth demands
Scale every stage	0.4978	0.4349	0.0466	0
Conditional (block floating point)	0.08273	0.06056	1.12	0.164
No scaling — grow the word	0.4426	0.3704	13.3	3.73

The growth column is measured on a noise-like input, so it is far below the worst-case bound of N : a random input does not align in phase. **The measured figure is not a bound** — a single tone at a bin centre would reach the bound, and a design justified by this column alone would overflow on the first sine wave a customer applied. Unconditional scaling is safe and loses precision every stage. Block floating point recovers most of it at the cost of a magnitude detector and an exponent that must travel with the data — **and that exponent is an interface**, which a specification frequently forgets to mention.

The block-floating-point exponent is part of the output. A block that returns a mantissa array and keeps the exponent internal has returned meaningless numbers. This is a real and recurring integration bug: the FFT passes its own tests, in which the reference is scaled the same way, and fails in the system, where the next block assumes a fixed scale. **Any scaling that depends on the data must appear in the port list.**

Problem. An OFDM receiver uses a 2048-point FFT. The input is an ADC output with 10 effective bits. How many bits should the FFT carry internally, and why is ‘ $10 + \log_2 2048 = 21$ ’ the wrong answer?

Solution. It is wrong in both directions. It is too pessimistic because the worst-case growth of N assumes every input conspires to align in phase at one output bin; for a noise-like OFDM signal the growth is closer to $\sqrt{N}$, about 5.5 bits, and unconditional scaling by 2 per stage over-attenuates such a signal by the same factor. It is too optimistic because it accounts only for range and not for the *accumulated quantisation noise* of the twiddle multiplies, which adds roughly half a bit per stage of precision loss. The correct procedure is Part X1's: state the end-to-end metric (for OFDM, the EVM the constellation demands), then sweep the internal word length against that metric and read off the knee. **The answer is a measurement, and it depends on the signal statistics, which is why an FFT IP block's datasheet must state the input statistics its SQNR figure was measured with.**

X6.4 Twiddle factors: the quiet memory

Table 250. Twiddle-factor ROM: full table vs. one-eighth with symmetry, 16-bit I and Q

N	Full entries	Full ROM (kB)	$\frac{1}{8}$ entries	$\frac{1}{8}$ ROM (kB)	Saving
256	128	0.5	33	0.129	3.88
1,024	512	2	129	0.504	3.97
4,096	2,048	8	513	2	3.99
16,384	8,192	32	2,049	8	4
65,536	32,768	128	8,193	32	4

The eighth-table exploits the symmetries of the unit circle; recovering the other seven octants costs a few multiplexers and a conditional negate and swap. For $N = 65\,536$ the difference is between a ROM that fits on a corner of the block and one that dominates it.

Undergraduate review · The symmetries, so the multiplexer logic makes sense. $W_N^k = e^{-2\pi i k/N}$ traces the unit circle clockwise. Cosine is even and sine is odd about the real axis, giving the lower half from the upper half; the quarter-turn identity exchanges sine and cosine, giving the second quadrant from the first; and the eighth-turn identity does the same within a quadrant. So the ROM stores angles from 0 to $\pi/4$ and the address decoder computes three bits — which octant — that control a swap of the I and Q outputs and two sign inversions. The whole recovery is combinational and adds perhaps two gate delays, against a ROM eight times smaller.

Problem. Instead of a ROM, twiddles can be generated by a CORDIC rotator or by a recursive oscillator $w[n+1] = w[n] \cdot W$. When is each appropriate?

Solution. The recursive oscillator is the cheapest — one complex multiply per twiddle — and is **unusable in a fixed-point pipeline** because it is a marginally stable recursion: quantisation error accumulates in both magnitude and phase, and over the thousands of twiddles of a large transform the magnitude drifts away from unity. It is acceptable only with periodic re-seeding from a small ROM, which is a hybrid rather than a replacement. CORDIC is exact to its iteration count and costs only shifts and adds, making it attractive in FPGA fabric where multipliers are a scarce hard resource but LUTs are plentiful; it costs latency, which a pipelined design can absorb. **The ROM wins in ASIC**, where a small compiled ROM is dense and the alternative spends timing budget. As so often, the right answer is set by which resource the target technology makes expensive, not by any property of the algorithm.

X7. Power and Energy, Worked

A design house is asked for three numbers about power: how much the block burns, how much of that is unavoidable, and what a customer can do about it. All three are computable, and a vendor who can produce them with their assumptions stated is selling something the competitor who quotes a single milliwatt figure is not.

X7.1 The three terms

Where the joules go

	Step	Justification
1	Charging a node of capacitance C to V takes CV^2 from the supply, of which $CV^2/2$ is stored and $CV^2/2$ is dissipated in the pull-up.	<i>Integrate iv over the transient; the result is independent of the resistance, which is why making transistors faster does not save switching energy.</i>
2	Discharging dissipates the stored half in the pull-down.	<i>So a full cycle costs CV^2, and a $0 \rightarrow 1 \rightarrow 0$ pair is one cycle.</i>
3	$P_{\text{dyn}} = \alpha CV^2 f$, with α the probability a node switches per clock.	<i>Rate times energy. α is the only term the RTL designer controls directly, and it is the term power estimates get wrong.</i>
4	P_{short} arises while both devices conduct during a transition; it scales with input slew.	<i>Typically 5–15 % of dynamic. Controlled by slew limits, not by architecture.</i>
5	$P_{\text{leak}} = V \cdot I_{\text{off}}$, with $I_{\text{off}} \propto e^{-V_{\text{th}}/(nkT/q)}$.	<i>Subthreshold conduction. Exponential in threshold and in temperature, which is why leakage is a thermal-runaway risk and dynamic power is not.</i>

Worked example 15. A gate-level power estimate from first principles

Given. A block with 200 000 gates, average switched capacitance 1 fF per gate, $V = 0.8$ V, $f = 1$ GHz, activity factor $\alpha = 0.15$. Clock network adds 30 % and its α is 1.

Method. Apply $\alpha CV^2 f$ to the logic and to the clock separately, because their activity factors differ by nearly an order of magnitude and averaging them is the commonest source of a wrong estimate.

Logic dynamic power	19200 mW
Clock network capacitance (30 % of logic)	60000 pF
Clock dynamic power ($\alpha = 1$)	38400 mW
Clock as a fraction of total dynamic	66.7 %
Total dynamic	57600 mW
Energy per cycle	57600 pJ

How this is got wrong. By applying one activity factor to the whole design. The clock toggles every cycle by definition; logic in a typical datapath toggles on ten to twenty per cent of cycles. An estimate that uses $\alpha = 0.2$ uniformly understates the clock by 5× and, since the clock here is two thirds of the total, understates the block by a factor approaching two. **Clock gating is the first power optimisation for exactly this reason**, and its benefit is visible in this table before any tool is run.

X7.2 Voltage scaling: the quadratic and its limit

Table 251. Voltage scaling with an α -power-law delay model ($V_{th} = 0.30$ V, $\alpha = 1.3$), normalised to 1.0 V

V_{dd} (V)	Relative delay	Relative f_{max}	Relative power at f_{max}	Relative power at fixed f	Relative energy per operation
1	1	1	1	1	1
0.9	1.1	0.9093	0.7366	0.81	0.8908
0.8	1.239	0.8071	0.5166	0.64	0.7929
0.7	1.449	0.6902	0.3382	0.49	0.71
0.6	1.805	0.554	0.1994	0.36	0.6499
0.5	2.548	0.3924	0.0981	0.25	0.6371
0.4	5.02	0.1992	0.03187	0.16	0.8032

The last column is the one that matters for a battery: energy per operation falls monotonically as the voltage drops, which is why near-threshold operation is attractive, while the frequency column says what it costs in throughput. Leakage is deliberately excluded here and X7.3 puts it back.

Figure 32. Energy per operation and maximum frequency against supply. The curves cross; where they cross is a design decision, not a fact.

Graduate Parallelism converts the voltage curve into a genuine win, and this is the single most important architectural consequence of the table above. Suppose a block must deliver throughput T . Run one copy at 1.0 V, or two copies at the voltage that halves the frequency. The two copies have twice the capacitance but each switches half as often per unit of work, so dynamic power is $2 \times (V'/V)^2 \times \frac{1}{2} = (V'/V)^2$ of the original. From the table, halving the frequency permits roughly a 0.65 V supply, giving about 0.42× the power for the same throughput at rather more than twice the area. **This calculation is the reason modern chips are wide and slow rather than narrow and fast**, and it is worth being able to do it on a whiteboard.

X7.3 Leakage, and why it changes the shape of everything

Table 252. Subthreshold leakage against temperature, normalised to 25 °C ($V_{th} = 0.30$ V, $n = 1.3$), and its share of a block that is 20 % leakage at room temperature

T (°C)	nkT/q (mV)	Relative leakage	Leakage share of total (%)
0	23.54	0.44	9.9
25	25.69	1	20
50	27.85	2	33.4
75	30	3.63	47.6
100	32.15	6.08	60.3
125	34.31	9.54	70.5

Computed from the subthreshold exponential alone; DIBL and gate leakage would steepen it further. The share column shows why a block that is a fifth leakage on the bench can be nearly half leakage in a hot enclosure.

Leakage and temperature form a positive feedback loop. Leakage raises power, power raises junction temperature, and higher temperature raises leakage exponentially. Below a certain thermal resistance the loop has a stable operating point; above it there is none, and the part runs away. This is not a theoretical concern in high-leakage processes: it is why datasheets specify a maximum junction temperature *and* a maximum case-to-ambient thermal resistance, and why a customer who improves cooling is not merely buying margin but may be buying stability. An IP vendor should state the leakage current at the maximum rated temperature, not at 25 °C.

Table 253. Power reduction techniques, what each attacks, and what it costs

Technique	Attacks	Typical saving	Cost	Who decides
Clock gating	α on the clock tree	20–40 %	A few gates; timing on the enable	The RTL designer — automatic gating catches most of it
Operand isolation	α in unused datapath	5–15 %	Muxes in the datapath	RTL designer
Multi- V_{th} cells	Leakage	2–5× on leakage	Slower cells on non-critical paths	Implementation, automatic
Power gating	Leakage, to near zero	>90 % when idle	Switch area, IR drop, wake latency, state retention	Architecture — it changes the reset and verification plan
DVFS	V^2f	2–5× at low load	Regulator, level shifters, characterisation at every operating point	System, with IP support
Architectural parallelism	V^2 via lower f	2–3×	Area, latency	Architecture, early — it cannot be retrofitted
Memory banking / sub-banking	C per access	10–30 % of memory power	Decode logic, floorplan	Architecture

Worked example 16. The savings are not additive — a worked composition

Given. A block is 100 mW: 60 mW clock, 25 mW logic, 15 mW leakage. Clock gating removes 60 % of clock power; multi- V_{th} removes 60 % of leakage; operand isolation removes 30 % of logic power.

Method. Apply each to its own term and re-total. Then compute what a naive addition of the three quoted percentages would have predicted.

Clock after gating	24 mW
Logic after isolation	17.5 mW
Leakage after multi- V_{th}	6 mW
New total	47.5 mW
Actual saving	52.5 mW
Actual saving (%)	52.5 %
Naive sum of the three quoted percentages	150 %
Clock share before / after	60% / 50.5%

How this is got wrong. By adding percentages that are percentages of different things. Each technique reduces one term, and after it has done so that term is a smaller share, which is why the second technique applied always returns less than its headline. The corollary is a procedure: **always attack the largest term first**, re-profile, and only then choose the next technique. A power plan written as a list of techniques without a breakdown to apply them to is not a plan.

Problem. A customer reports that your block consumes $2\times$ the datasheet figure. List the measurements that distinguish the possible causes, in the order you would make them.

Solution. 1. Compare activity factors. The datasheet figure was measured with some stimulus; ask what theirs is. A block specified on random data and used on highly correlated data — or the reverse — can differ by a factor of two with nothing wrong. This is the most common cause and the cheapest to check. **2. Check the clock-gating enables are actually asserting**, by toggling coverage or by a scope on the gated clock; an integration that ties an enable high disables the largest single saving. **3. Split dynamic from leakage** by measuring at two temperatures: leakage doubles over 40 °C or so and dynamic does not, so two points separate the terms. **4. Check the supply** — a 10 % overvoltage is a 21 % dynamic increase. **5. Only then suspect the block.** Note that the first four are questions about the customer's system, and asking them requires having recorded your own measurement conditions; a datasheet power figure without its stimulus, voltage and temperature is unfalsifiable and therefore worthless in exactly this conversation.

X8. The Mathematics of Verification, Worked

Three questions decide a verification plan: how long must random stimulus run to reach a coverage target, how many bugs remain when the discovery rate flattens, and what a bug costs at each stage. All three have arithmetic answers. None of them is a substitute for judgement, but a plan that contradicts the arithmetic needs a reason.

X8.1 Coverage closure is a coupon-collector problem

How long random stimulus takes to hit every bin

	Step	Justification
1	Suppose there are n coverage bins, each hit with equal probability $1/n$ by an independent random transaction.	<i>The idealisation. Real bins are neither equiprobable nor independent, and X8.2 measures what that does.</i>
2	After the k th distinct bin is hit, the probability that the next transaction hits a new bin is $(n-k)/n$.	<i>Uniformity.</i>
3	So the expected wait for the next new bin is $n/(n-k)$.	<i>Mean of a geometric distribution.</i>
4	Total expected transactions = $n \sum_{k=1..n} 1/k = nH_n \approx n(\ln n + 0.577)$.	<i>Sum the waits; H_n is the harmonic number.</i>
5	For 90 % of the bins, the sum truncates and the cost is only $n \ln 10 \approx 2.3n$.	<i>Σ from 1 to $0.9n$ of $1/(n-k)$. This is the whole shape of every coverage curve you have ever seen: cheap to 90 %, expensive to 100 %.</i>

Table 254. Expected random transactions to reach a coverage target, equiprobable bins

Bins n	To 90 %	To 99 %	To 100 %	Cost of the last 10 % as a multiple of the first 90 %
100	230	460	518	2.25
1,000	2,302	4,605	7,485	3.25
10,000	23,025	46,051	97,876	4.25
100,000	230,258	460,517	1,209,014	5.25

The last column is roughly constant at about four, independent of n . The final ten per cent of coverage costs three times what the first ninety did, every time, and that is before the bins turn out to be unequal.

Figure 33. The coupon-collector curve for 1000 bins. It is not that the last bins are harder to hit by design; they are harder to hit because there are fewer of them left to hit by accident.

Worked example 17. Sizing a regression from a coverage model

Given. A block has 8000 coverage bins. One simulation runs 40 000 transactions and takes 6 minutes. The target is 99 % coverage. 200 simulations can run in parallel.

Method. Convert the bin count to a transaction count with the coupon-collector estimate, then to simulations, then to wall-clock time.

Transactions to 99 %	36,841
Simulations needed	1
Serial machine-time	0.1 hours
Wall clock on 200 in parallel	< 1 run — the pool is not the limit
Transactions to 100 % (harmonic sum)	76,515
Simulations for 100 %	2

How this is got wrong. By concluding that random stimulus will therefore close coverage. The model assumes every bin is reachable by random stimulus with equal probability. In practice a handful of bins require a specific sequence — a FIFO full while a retry is in flight and a parity error arrives — whose random probability is not $1/n$ but 10^{-9} . **Those bins never close randomly and no amount of compute changes that;** they close with directed tests or constrained scenarios. The arithmetic above tells you how much compute to buy for the easy 99 %, and identifying the remaining bins as requiring direction is the actual verification engineering.

Table 255. Measured transactions to 99 % coverage of 1000 bins as the bin probabilities are made unequal

Skew parameter	Most likely : least likely bin	Transactions measured	Multiple of the equiprobable estimate
0	1	6,000	1.3
0.5	1.65	6,000	1.3
1	2.72	6,000	1.3
1.5	4.47	8,000	1.74

Skew parameter	Most likely : least likely bin	Transactions measured	Multiple of the equiprobable estimate
2	7.37	8,000	1.74

An exponential weighting with the stated skew, measured by simulation with seed 9. Even a 7:1 spread between the most and least likely bin multiplies the cost noticeably; real constraint solvers produce far larger spreads than that, which is why **coverage convergence is slower than any model predicts and why the remedy is to reshape the constraints, not to buy machines.**

X8.2 Bug discovery curves and when to stop

Bugs are found at a rate that decays roughly exponentially with effort, because the easy ones go first. Fitting that decay gives an estimate of how many remain — an estimate that is crude, defensible, and far better than the alternative, which is a feeling.

Table 256. An exponential bug-discovery model: 240 latent bugs, decay constant 0.18 per week

Week	Cumulative found	Bugs found this week	Estimated remaining	Remaining (%)
2	72	30.1	167	69.8
4	123	21	116	48.7
6	158	14.7	81	34
8	183	10.2	56	23.7
10	200	7.14	39	16.5
12	212	4.98	27	11.5
16	226	2.43	13	5.61
20	233	1.18	6	2.73

The parameters are illustrative; the method is not. Fit the two parameters to your own weekly find-rate data and the extrapolation is a real estimate with a real confidence interval.

Figure 34. The two curves sum to a constant by construction. The decision to tape out is the decision that the lower curve is acceptable.

The find-rate falling is ambiguous and this is where projects deceive themselves. A falling rate means either that the bugs are running out or that the *testing* is running out — the same tests re-run on the same stimulus find nothing new whether or not bugs remain. The two are distinguished by a measurement, not by an argument: **introduce new stimulus or a new checker and see whether the rate recovers.** Mutation testing does this systematically by injecting known faults and asking what fraction the existing suite catches; a suite that catches 60 % of injected faults is telling you your find-rate curve has flattened for the wrong reason. This repository runs exactly such a hunt against its own checks.

Table 257. Relative cost of finding one bug at each stage, and the cost of letting 2 % of 240 bugs reach that stage

Stage found	Relative cost	vs. spec review	Cost of 2 % escaping to here (relative units)
Specification review	1	—	4.8
Modelling / C++ reference	3	3×	14.4
Block-level simulation	10	10×	48
Chip-level simulation	40	40×	192
Emulation / FPGA prototype	100	100×	480
First silicon bring-up	1,000	1000×	4800
Customer escape	10,000	10 000×	48000

*The multipliers are the industry's rule of thumb and vary by an order of magnitude between sources; the **shape** is what is robust. It is the reason a modelling team that catches specification ambiguities pays for itself many times over, and the reason design houses invest in the left-hand rows.*

Worked example 18. Is another month of verification worth it?

Given. At week 12 the model above estimates 28 bugs remaining. A month of verification costs 4 engineer-months. Each bug that reaches silicon costs, on average, 1 engineer-month of debug; a respin costs 40 engineer-months plus three months of schedule, and the probability of a respin is roughly the probability that at least one remaining bug is functional-critical, estimated at 5 % per remaining bug.

Method. Compute the expected cost of stopping now against the expected cost of continuing, using the discovery model to say how many bugs the extra month removes.

Bugs remaining at week 12	27
Bugs remaining at week 16	13
Bugs removed by the extra month	14
P(no respin) if we stop now	0.242
P(no respin) if we continue	0.501
Expected respin cost now (engineer-months)	30.33
Expected respin cost after one more month	19.96
Saving from the extra month	10.37
Cost of the extra month	4
Verdict	continue

How this is got wrong. By treating the model's parameters as known. The decay constant is fitted from noisy weekly counts and its uncertainty propagates into the remaining-bug estimate, which sits inside an exponent. The right use of this calculation is not to produce a verdict but to find out *which assumption the verdict is sensitive to*: here it is the 5 % criticality figure, and that figure can be improved by classifying the bugs already found, which is free. **Do the sensitivity analysis and go and measure the sensitive term.**

Problem. Your regression has 100 % code coverage and 98 % functional coverage, and has found no new bug in three weeks. A reviewer asks for evidence that the suite would catch a bug if one existed. What do you provide?

Solution. Code coverage is the weakest of the three and answering with it is the mistake: it shows lines executed, not behaviour checked, and a testbench with the checkers disabled reaches 100 %. The evidence a reviewer should accept is **fault injection**: take the design, introduce a set of realistic mutations — invert a comparison, drop a reset term, change a FIFO threshold by one, delete a wait state — and report the fraction the existing suite catches, with the escapes listed and explained. A suite that catches 95 % of mutations has made a falsifiable claim about itself. Supplement it with **checker coverage** (did each assertion ever fire in a passing run? an assertion that never even evaluated its antecedent is not checking anything) and with the **bug-find-rate recovery test** above: add genuinely new stimulus and see whether the rate moves. **Every one of these is a measurement of the testbench rather than of the design**, which is precisely what was asked for.

Problem. Formal verification proves a property over all inputs. Why does a project still simulate?

Solution. Three reasons, in decreasing order of how often they bite. **Capacity**: proofs complete on control logic, arbiters, FIFOs and protocol interfaces, and commonly do not on a datapath with wide multipliers or on a whole subsystem; what comes back is a bounded proof, which is a very good simulation and not a proof. **Specification**: a formal tool proves the properties you wrote. A missing property is an unproven behaviour, and there is no coverage metric for ‘properties I did not think of’ — though mutation coverage of the property set comes closest. **Environment**: proofs need constraints to exclude illegal inputs, and an over-constraint silently removes the case that would have failed — the formal equivalent of a false-green, and the one that has ended more than one post-silicon investigation. The two techniques are complementary in a specific way worth remembering: **formal is strong where state space is deep and narrow, simulation is strong where it is shallow and wide.**

X9. Computer Arithmetic Beyond the Adder, Worked

Addition and multiplication are solved problems with known structures. Division, square root, and the transcendental functions are not: each admits several algorithms with genuinely different latency, area and accuracy, and choosing among them is a recurring task for anyone specifying a datapath. This part computes the trade-offs instead of listing them.

X9.1 Adders: the latency–area curve, computed

Table 258. Adder structures: delay in gate levels and area in full-adder equivalents

Width n	Ripple delay	Kogge–Stone delay	Kogge–Stone area	Carry-select delay ($\sqrt{n}$ blocks)	Carry-select area
8	8	8	12	5	16
16	16	10	32	8	32
32	32	12	80	11	64
64	64	14	192	16	128
128	128	16	448	22	256

Delays are counted in two-input gate levels from the standard prefix constructions; they are architectural counts, not library timing. Kogge–Stone is logarithmic in delay and $n \log n$ in area and wiring — and the wiring, not the gates, is what makes it expensive in a real floorplan.

Graduate · Why the prefix-adder family is a design space rather than a single answer. Every parallel-prefix adder computes the same carry prefixes; they differ in how the prefix tree is shaped, and the shape trades three quantities against each other: logic depth, fan-out, and wiring tracks. Kogge–Stone minimises depth at maximum wire count; Brent–Kung minimises wires at twice the depth; Han–Carlson interleaves the two and sits between; Ladner–Fischer trades fan-out for wires. In a modern process **the wiring term usually dominates**, so the textbook's favourite (Kogge–Stone) is often not the synthesiser's choice, and a designer who insists on it by instantiation can make the block slower. The right procedure is to let the tool choose from its library and to check the result, not to specify the topology in the RTL.

X9.2 Multipliers: partial products and how to not add them

Table 259. Partial-product counts and reduction depth

Operand width n	Simple PP rows	Radix-4 Booth rows	Radix-8 Booth rows	Wallace 3:2 reduction levels (from radix-4)	Approx. full adders in the tree
8	8	5	4	3	24
16	16	9	7	4	86
24	24	13	9	5	187
32	32	17	12	6	326
53	53	28	19	7	890

Radix-8 Booth needs a $3\times$ multiple, which costs an adder and a carry chain up front; it pays only when the row saving outweighs that, which for $n \geq 32$ it usually does. The 53 row is the IEEE-754 double-precision significand.

Worked example 19. Why a multiplier ends in one wide adder

Given. A 32×32 multiplier built as radix-4 Booth encoding plus a carry-save reduction tree.

Method. Count the stages and see where the delay goes. Carry-save addition has *constant* delay per level regardless of width, because no carry propagates; only the final conversion from carry-save to binary needs a carry-propagate adder.

Booth rows	17
Reduction levels to reach 2 rows	6
Delay of the tree (≈ 2 gate levels per level)	12 gate levels
Final 64-bit carry-propagate adder (Kogge–Stone)	14 gate levels
Final adder as a fraction of total delay	53.8 %

How this is got wrong. By optimising the reduction tree and leaving the final adder to the synthesiser's default. The final adder is a third of the delay of the whole multiplier, and it is the one part that is a plain carry-propagate problem. It is also the reason **a multiply-accumulate is cheaper than a multiply followed by an add**: keep the product in carry-save form, feed it into the accumulator's reduction tree, and pay for exactly one carry-propagate adder at the end of the whole accumulation rather than one per operation. Any datapath that multiplies and then sums should be examined for this.

X9.3 Division and square root: digit recurrence against Newton

Table 260. Two families, and what each is for

	Digit recurrence (SRT)	Multiplicative (Newton–Raphson, Goldschmidt)
Produces	One radix- r digit per iteration	Doubles the number of correct bits per iteration
Iterations for 53 bits	27 at radix 4	About 4 from an 8-bit seed
Per-iteration cost	A small adder and a quotient-digit selection table	Two full multiplies
Exact remainder	Yes — available for free	No; needs a final correction step
Correct rounding	Straightforward from the remainder	Requires care ; this is where implementations go wrong
Latency	Long, predictable	Short if multipliers are already there
Reuses	Nothing	The existing multiplier array
Chosen when	Area matters, or the remainder is needed (integer division, modulo)	A fast multiplier already exists (every FPU)

The Pentium FDIV bug was a digit-selection table with five missing entries. An SRT divider chooses each quotient digit from a lookup indexed by truncated partial remainder and divisor; the table has redundant regions so that a slightly wrong estimate can be corrected later, which is exactly what makes the algorithm fast and exactly what makes a missing entry hard to find by random testing. The entries were unreachable for almost all operand pairs. The lesson for a verification plan is specific and permanent: **a table-driven arithmetic unit must be verified over the table's index space, not over the operand space.** Random operands reach the interesting table entries with probability near zero; enumerating the index space takes minutes.

Table 261. Iteration counts: Newton–Raphson against SRT

Result bits	Seed table bits	Newton iterations	Multiplies	SRT radix-4 iterations	SRT radix-8 iterations
24	8	2	4	12	8

Result bits	Seed table bits	Newton iterations	Multiplies	SRT radix-4 iterations	SRT radix-8 iterations
24	12	1	2	12	8
24	16	1	2	12	8
53	8	3	6	27	18
53	12	3	6	27	18
53	16	2	4	27	18
113	8	4	8	57	38
113	12	4	8	57	38
113	16	3	6	57	38

Newton's iteration count is logarithmic in the precision and the seed table's size trades directly against it — four extra table bits routinely remove an entire iteration, which is two multiplies. **This is the cheapest optimisation in the whole unit** and is frequently left on the table.

Problem. A block needs $y = a/b$ where b changes rarely and a changes every cycle. What is the right structure?

Solution. Not a divider. Compute $r = 1/b$ once, when b changes, and multiply every cycle. The reciprocal can take as long as it likes — a slow iterative unit, or even a microcoded sequence — because it is off the critical path, and the per-cycle cost collapses to one multiply. **The general principle is worth naming: look for the operand that changes slowly and move work onto it.** The same observation produces the coefficient-folding in a fixed-coefficient FIR, the precomputed tables in a modular-arithmetic unit, and the slow adaptation loop of a SerDes equaliser. The one caution is accuracy: $a \cdot (1/b)$ is not correctly rounded even when both operations are, so a unit claiming IEEE compliance cannot take this shortcut without a correction step.

X9.4 CORDIC: rotations without multipliers

Why the strange constants work

	Step	Justification
1	A rotation by θ is $(x\cos\theta - y\sin\theta, x\sin\theta + y\cos\theta)$.	<i>Definition.</i>
2	Factor out $\cos\theta$: the rotation becomes $\cos\theta$ times a shear with $\tan\theta$.	<i>Algebra. The scale factor is now separate from the shape.</i>
3	Choose θ_i with $\tan\theta_i = 2^{-i}$. Then the shear is two shifts and two adds.	This is the whole trick: restrict the allowed angles so the multiplication becomes a shift.
4	Any angle in the convergence range is reachable as $\Sigma\pm\theta_i$.	<i>Because $\theta_i < \Sigma_{j>i}\theta_j$, so the remaining steps can always correct an overshoot — the same redundancy argument that makes SRT division work.</i>
5	The accumulated scale $\Pi\cos\theta_i \rightarrow 0.607253$ is independent of the angle , because every step rotates by the same magnitude and only the sign varies.	<i>So it can be compensated once, at the end, or folded into surrounding coefficients for free.</i>

Table 262. Measured CORDIC accuracy against iteration count (rotation mode, 41 angles)

Iterations	Scale factor K	Max error in cos	Effective bits	Adds
8	0.60725911	0.00453	7.79	16
12	0.60725296	2.65×10^{-4}	11.9	24
16	0.60725294	2.17×10^{-5}	15.5	32

Iterations	Scale factor K	Max error in cos	Effective bits	Adds
20	0.60725294	9.02×10^{-7}	20.1	40
24	0.60725294	7.05×10^{-8}	23.8	48

One bit of accuracy per iteration, exactly as the theory predicts, and the scale factor converges quickly to its limit. The last column is the cost: two adds and two shifts per iteration and no multiplier anywhere.

Undergraduate review · The three CORDIC modes, and what each computes. In *rotation* mode the algorithm drives the angle accumulator to zero and the coordinates come out rotated — giving sine and cosine, and the complex rotation a mixer or an FFT twiddle needs. In *vectoring* mode it drives y to zero instead, and what accumulates is the original angle — giving arctangent and magnitude, which is exactly the operation a Cartesian-to-polar conversion, an AM detector or a phase detector performs. Substituting hyperbolic angles ($\tanh$ instead of $\tan$) gives a third mode that computes exponentials, logarithms and square roots, with some iterations repeated to preserve convergence. **One structure, three modes, most of the transcendental functions a DSP block needs** — which is why CORDIC survives in fabric where multipliers are the scarce resource.

X9.5 Floating point: what the standard actually requires

Table 263. Floating-point formats in current use

Format	Total bits	Exponent bits	Stored mantissa bits	Significand bits (with hidden 1)	Machine epsilon	Decimal digits
binary16 (half)	16	5	10	11	4.88×10^{-4}	3.31
bfloat16	16	8	7	8	0.00391	2.41
binary32 (single)	32	8	23	24	5.96×10^{-8}	7.22
TF32	19	8	10	11	4.88×10^{-4}	3.31
binary64 (double)	64	11	52	53	1.11×10^{-16}	16
FP8 E4M3	8	4	3	4	0.0625	1.2
FP8 E5M2	8	5	2	3	0.125	0.903

bfloat16 and *binary16* are the same width and differ entirely in how they split it: *bfloat16* keeps *binary32*'s exponent range and throws away precision, which is the right trade for neural-network training because the failure mode there is overflow of a gradient, not rounding of a weight.

Worked example 20. Why $0.1 + 0.2 \neq 0.3$, in bits

Given. IEEE-754 binary64 arithmetic.

Method. 0.1 and 0.2 are not representable: in binary they are infinite repeating fractions, so each is rounded to 53 significant bits. The sum of the two rounded values is then itself rounded. Print the exact decimal expansions.

0.1 stored as	0.1000000000000000555
0.2 stored as	0.2000000000000000110
0.1 + 0.2 =	0.3000000000000000441
0.3 stored as	0.29999999999999998890
Difference	5.55×10^{-17}
Difference in units in the last place	1

How this is got wrong. By concluding that floating point is unreliable. It is exactly reliable: every operation above returned the correctly rounded result, and the standard guarantees that. What is unreliable is the assumption that decimal literals are representable. The consequences for hardware verification are direct: a bit-exact comparison against a reference model is only meaningful if both use the same rounding mode and the same order of operations, **and floating-point addition is not associative**, so a reference model that sums an array in a different order than the RTL will disagree with it while both are correct. Specify the summation order, or specify a tolerance and justify it.

Problem. A neural-network accelerator uses bfloat16 multipliers with binary32 accumulation. Why not accumulate in bfloat16 too?

Solution. Because accumulation is where precision is lost and multiplication is not. A bfloat16 multiply of two 8-bit significands produces a 16-bit exact product, and rounding it back to 8 bits costs one rounding. Summing N such products in bfloat16 costs N roundings, each of half an LSB of a number with only 8 significand bits, and — worse — once the running sum is 2^8 times larger than the next term, that term is **absorbed entirely** and contributes nothing. For N in the hundreds or thousands, which a convolution reduction routinely is, the sum silently stops growing. Binary32 accumulation has 24 significand bits and pushes the absorption threshold out by 2^{16} . **The general rule is that a reduction needs more precision than its operands**, which is why every practical mixed-precision unit, from a DSP MAC to a tensor core, is asymmetric in exactly this way.

X10. Memory: The Block That Decides the Floorplan

In most IP blocks the memory is the largest single object, the slowest path, and the thing that cannot be changed late. It is also the part of a design that RTL hides most completely: a two-dimensional array in SystemVerilog becomes, in silicon, a compiled macro with a fixed aspect ratio, a fixed number of ports and its own timing model. This part computes what that substitution costs.

X10.1 The bit cell and what follows from it

Table 264. Storage cells compared

Cell	Transistors / bit	Relative area	Volatile	Read	Used for
6T SRAM	6	1	Yes	Non-destructive	Caches, buffers, everything on-chip
8T SRAM	8	~1.3	Yes	Separate read port	Low-voltage operation — decouples read and write stability
Dual-port (2RW)	8–10	~1.8–2	Yes	Two ports	FIFOs across clock domains
Register file cell	~8–12	1.5–3	Yes	Many ports	Small, highly ported storage
1T-1C DRAM	1 + capacitor	~0.15	Yes, needs refresh	Destructive — must write back	Main memory, eDRAM
ROM (via / contact)	1 or 0	~0.1	No	Non-destructive	Twiddles, microcode, constants
Flip-flop	~20–24	4–5	Yes	—	What synthesis gives you if you do not instantiate a macro

Worked example 21. The cost of forgetting to instantiate a RAM

Given. A 4 kB buffer, 32 768 bits. The 6T cell is $0.03 \mu\text{m}^2$; a flip-flop with its multiplexer occupies roughly $150\times$ a bit cell once the write-enable logic is counted.

Method. Compute both areas and the array overhead. SRAM macros carry decoders, sense amplifiers and control that a small array cannot amortise; assume 40 % overhead at this size.

Bit-cell area	$983 \mu\text{m}^2$
Compiled macro with 40 % overhead	$1376 \mu\text{m}^2$
Same storage in flip-flops	$1.475 \times 10^5 \mu\text{m}^2$
Ratio	$107\times$
Flip-flop clock power penalty (all bits clocked every cycle)	very large — every bit is on the clock tree

How this is got wrong. By writing an array in RTL and letting synthesis decide. Synthesis will infer flip-flops unless the coding style matches the inference template exactly — and the template differs between tools and between memory compilers. The failure is quiet: the design works, meets timing, and is a hundred times too large. **Always check the synthesis report for inferred registers against your expected memory instances**, and prefer explicit instantiation with a wrapper for anything above a few hundred bits.

X10.2 Aspect ratio, banking and the access-energy curve

Table 265. Same 32 768 bits, six aspect ratios (relative units)

Words (depth)	Bits per word	Bit-line length	Word-line length	Relative access energy	Relative access delay
128	256	128	256	0.23	14.8
256	128	256	128	0.307	20
512	64	512	64	0.538	27.1
1,024	32	1,024	32	1.04	37
2,048	16	2,048	16	2.05	50.8
4,096	8	4,096	8	4.1	70

A tall narrow array has long bit lines, which cost energy and delay; a short wide one has long word lines and wastes energy activating bits it will not return. **The optimum is in the middle and memory compilers know it**, which is why a compiler refuses extreme aspect ratios and folds internally instead.

Graduate · Sub-banking is why a 1 MB cache does not cost 32× the energy of a 32 kB one. A large array is built as many small arrays with a hierarchical decoder, and an access activates one of them. Energy per access therefore grows roughly with the *square root* of capacity rather than linearly, and the same structure bounds the delay growth. This is the reason capacity-versus-energy intuitions borrowed from a small block do not transfer, and the reason a cache model that charges energy proportional to size will mispredict a memory-bound design badly. **When you need real numbers, use a memory compiler's datasheet or a model such as CACTI** — and state which, because the two disagree.

X10.3 Multi-port memory: three ways, all of them compromises

Table 266. Getting more ports than the compiler offers

Technique	Ports obtained	Area cost	Restriction
True multi-port cell	$nRmW$	Grows as $(n+m)^2$ — wires per cell	Only 1RW and 2RW are usually in the compiler library
Banking by address	n accesses if to different banks	Decode and crossbar	Conflicts stall — needs arbitration and back-pressure
Replication (one copy per reader)	$nR1W$	$n \times$ the array	Writes must go to every copy
Double clocking	2 accesses per functional cycle	None in area	Halves the frequency budget ; needs a clean 2× clock
XOR / LVT multi-port	$nRmW$ from 1RW banks	$m(n+m)$ banks plus a live-value table	Complexity; well suited to FPGA, rarely worth it in ASIC

Worked example 22. A register file's port count is a quadratic cost

Given. A 32-entry $\times$ 64-bit register file for a 2-wide machine: 4 read ports and 2 write ports.

Method. Model the cell area as growing with the square of the total port count, which is the standard first-order model because each port adds a bit line and a word line to every cell.

Ports	6
Area relative to a 1R1W cell	9 $\times$
Bits	2,048
If widened to 4-wide (8R4W): ports	12
Area relative to 1R1W	36 $\times$
Area penalty of doubling issue width	4 $\times$

How this is got wrong. By treating issue width as a free architectural parameter. Doubling it quadruples the register-file area and lengthens its access, which is one of the two reasons superscalar width stopped growing (the other is the scheduler's own quadratic wake-up logic). The architectural responses are all about avoiding the quadratic: clustering the register file and accepting a cross-cluster penalty, banking it by register number, or moving to a structure where most operands never enter the file at all. **A cost model that is quadratic in a parameter is a signal to change the structure, not to tune the parameter.**

X10.4 ECC: the arithmetic of protecting a memory

Why SECDED needs exactly the bits it needs

	Step	Justification
1	To correct a single error among k data bits, the syndrome must name one of $k+r$ positions or say 'no error'.	<i>Every correctable case needs its own syndrome value.</i>
2	So $2^r \geq k + r + 1$.	<i>The Hamming bound for single-error correction.</i>
3	Detecting double errors as well costs one more bit: an overall parity.	<i>With it, a double error gives a non-zero syndrome and even overall parity, which single errors never do.</i>
4	SECDED overhead is $r+1$ bits for k data bits.	<i>And because r grows logarithmically, wide words are far cheaper to protect than narrow ones — the single most useful consequence.</i>

Table 267. SECDED overhead against word width

Data bits k	Hamming bits r	SECDED bits	Overhead (%)	Total stored bits
8	4	5	62.5	13
16	5	6	37.5	22
32	6	7	21.9	39
64	7	8	12.5	72
128	8	9	7.03	137
256	9	10	3.91	266
512	10	11	2.15	523

Protecting a 64-bit word costs 12.5 %; protecting a 512-bit line costs 2 %. **This is why ECC is applied to cache lines and DRAM bursts rather than to bytes**, and why a design that must protect narrow fields should consider grouping them first.

ECC changes the timing path and the failure modes, not only the area. The syndrome must be computed and the correction applied before the data is used, which inserts an XOR tree — typically 3 to 5 gate levels for a 64-bit word — into the read path. At high frequency this forces the correction into a later pipeline stage, which means **the consumer must be able to tolerate a late correction or be stalled**, and that is an architectural decision, not an implementation detail. There is a second trap: a memory with ECC that is never scrubbed accumulates single-bit errors until two coincide in one word, at which point a correctable fault population becomes an uncorrectable event. **Scrubbing is part of the ECC design, not an optional extra**, and its period follows from the soft-error rate and the word count.

Table 268. Soft-error arithmetic at 1000 FIT/Mbit (one failure per 10⁹ device-hours per Mbit)

Memory (Mbit)	Errors per hour	MTBF (years, one device)	Errors per device-year	Errors per year across a million units
1	1.00×10^{-6}	114	0.00877	8766
4	4.00×10^{-6}	28.5	0.0351	35064
16	1.60×10^{-5}	7.13	0.14	1.40×10^5
64	6.40×10^{-5}	1.78	0.561	5.61×10^5
256	2.56×10^{-4}	0.446	2.24	2.24×10^6

The last column is the one a product manager needs. **A part that sees one upset per device-century produces thousands of field events per year across a large deployment**, which is why ECC appears in consumer parts and not only in servers. The FIT figure itself depends on altitude, process and cell design and must come from the foundry.

Problem. Your block has a 2 kB configuration RAM written once at boot and read every cycle thereafter. Does it need ECC, and of what kind?

Solution. It needs protection more than a data buffer does, for a reason that has nothing to do with its size: **a corrupted configuration bit is permanent and systematic**, where a corrupted data word is transient. An upset in a filter coefficient degrades every subsequent output, silently, until the next reboot, and there is no downstream check that will catch it. The economical answer is usually **parity plus a reload path** rather than full SECDED: since the contents are known and re-writable, detection is enough — flag the error, interrupt, and have software rewrite the block. That costs one bit per word instead of eight and needs no correction logic in the read path, so it does not disturb the timing at all. **Choose detection over correction whenever a recovery path exists**; the recovery path is usually cheaper than the correction hardware, and it also covers failures the ECC cannot, such as a corrupted address.

Problem. Why does a FIFO built from a dual-port SRAM need its pointers in flip-flops rather than in the same memory?

Solution. Because the pointers must be readable in the same cycle they are compared, and a synchronous SRAM read has a cycle of latency. The full and empty conditions gate the write and read enables of the current cycle, so a pointer that arrives a cycle late produces a FIFO that overflows by one entry under back-to-back traffic — a bug that appears only at full rate, which is to say only in the system and never in the unit test that writes one word at a time. **The general form of this trap is worth internalising: any state that participates in this cycle's flow-control decision cannot live behind a synchronous read port.** It is the same reason a cache tag array is read a cycle ahead of the data array, and the reason credit counters in an interconnect are registers however large the credit table becomes.

X11. Interconnect: Arbitration, Flow Control and Deadlock

An IP block that talks to anything talks through an interconnect, and the interconnect's properties leak into the block's specification whether or not the specification mentions them. The three that leak hardest are how bandwidth is shared, how back-pressure propagates, and whether the system can lock up. All three are computable and the third is provable.

X11.1 Credit-based flow control: sizing the buffer

Why the buffer must cover the round trip

	Step	Justification
1	The sender may transmit only while it holds credits; each transmission consumes one.	<i>Definition of credit-based flow control.</i>
2	A credit is returned when the receiver frees a buffer entry; the return takes t_{ret} to arrive.	<i>Physical delay: the return path is wires and pipeline stages like any other.</i>
3	For the sender never to stall while the receiver is draining, credits must outlast the round trip.	<i>Otherwise there is an interval in which the sender has no credit and the receiver has space.</i>
4	$N_{\text{buf}} \geq B \cdot \text{RTT}$, where B is the peak rate and RTT is forward latency plus return latency.	<i>The bandwidth–delay product. It is the same formula as a TCP window and for exactly the same reason.</i>
5	Any shortfall shows up as a throughput loss of $N_{\text{buf}} / (B \cdot \text{RTT})$, not as a functional failure.	<i>Which is why an undersized buffer is found in performance bring-up rather than in verification — late, and by the customer.</i>

Table 269. Credit buffer needed against pipeline depth, one flit per cycle

Forward stages	Return stages	Round trip (cycles)	Minimum credits	Buffer bytes at 32 B/flit	Throughput if only one credit is provided
1	1	2	2	8	0.5
2	2	4	4	16	0.25
4	4	8	8	32	0.125
8	8	16	16	64	0.0625
16	16	32	32	128	0.0312

The last column is what an under-provisioned link actually delivers: one flit per round trip. A four-deep pipeline with one credit runs at an eighth of the wire's rate, and nothing in the design is broken.

Worked example 23. A block on a pipelined AXI interconnect

Given. A DMA engine issues read bursts across an interconnect with 6 cycles of forward latency and 6 of response, at 500 MHz, 128-bit data, and must sustain 6 GB/s.

Method. Convert the required bandwidth into outstanding transactions via the bandwidth–delay product, then check it against the interface's ID width, which is what actually limits outstanding transactions on AXI.

Bytes per beat	16
Beats per second required	3.750×10^8
Cycles per second	5.000×10^8
Beats per cycle required	0.75
Round-trip latency	12 cycles
Outstanding beats needed	9
If bursts are 16 beats: outstanding bursts needed	1
Read data buffer required	144 B

How this is got wrong. By sizing the buffer for the burst and not for the round trip. A common specification says ‘one burst of read data’, which permits exactly one outstanding burst and throttles the engine to burst-length divided by round-trip — here about a quarter of the wire rate. The second frequent error is to size for the *average* latency: the interconnect's latency has a tail whenever another master is active, and a buffer sized for the mean stalls whenever the tail occurs. **Size for the latency at the load you will actually run at**, and state that load in the datasheet, because a customer whose system is busier than your bench will not reach your quoted bandwidth.

X11.2 Arbitration: fairness has a precise meaning and a cost

Table 270. Measured mean / maximum wait in cycles, four masters offering 0.5, 0.2, 0.15 and 0.1 requests per cycle, 200 000 cycles

Policy	M0 (busiest)	M1	M2	M3 (quietest)
Fixed priority	1.0 / 1	2.0 / 21	3.3 / 29	5.4 / 62
Round robin	1.6 / 4	1.5 / 4	1.5 / 4	1.5 / 4
Oldest first (LRG)	1.4 / 4	1.8 / 4	2.0 / 4	2.1 / 4

Simulated with seed 13. Fixed priority starves the low-priority masters when the high-priority one is busy — read M3's maximum. Round robin bounds everyone's wait; oldest-first minimises the maximum further at the cost of an age counter per requester.

Table 271. Arbitration policies and what each guarantees

Policy	Guarantees	Cost	Fails at
Fixed priority	Lowest latency for the top requester	A priority encoder — cheapest	Starvation: no bound for the bottom requester
Round robin	Bounded wait of $n-1$ grants	A rotating pointer	Does not respect differing bandwidth needs
Weighted round robin	Bandwidth in proportion to weights	Per-requester counters	Latency for a low-weight but urgent requester
Deficit round robin	Bandwidth proportion with variable-size requests	A deficit counter per requester	— this is the standard answer for packets

Policy	Guarantees	Cost	Fails at
Oldest first	Minimises maximum wait	Age counters and a comparison tree — the tree is the timing problem	Scaling: the comparison is $O(\log n)$ deep and wide
Lottery / ran- domised	Proportional in expectation	An LFSR	No bound , only an expectation — unacceptable for real-time

Graduate · **Quality of service is not a policy, it is two different requirements that must be separated before a policy can be chosen.** A display controller needs *guaranteed bandwidth* and tolerates latency, because it has a line buffer; a CPU fetching a cache miss needs *low latency* and consumes little bandwidth. One arbiter cannot serve both well with a single knob, which is why real interconnects separate them: a bandwidth regulator (a token bucket or a deficit counter) enforces the first, and a priority class enforces the second, with the regulator demoting a requester that exceeds its allocation so that its priority cannot starve anyone. **When writing an IP block's requirements, state which of the two you need;** 'high performance' is not an interconnect requirement and cannot be designed against.

X11.3 Deadlock: a property of the dependency graph

The four conditions, and which one hardware removes

	Step	Justification
1	Mutual exclusion: a resource is held by one holder at a time.	<i>True of every buffer; not removable.</i>
2	Hold and wait: a holder may request another resource while holding one.	<i>True of any pipelined request; removing it means allocating everything at once, which wastes buffers.</i>
3	No pre-emption: a buffer cannot be taken back.	<i>Removable — by dropping and retrying, which is what a network does and what an on-chip fabric usually cannot afford.</i>
4	Circular wait: the wait-for graph contains a cycle.	<i>This is the one hardware removes.</i> Break every cycle and deadlock is impossible regardless of the other three.
5	Virtual channels break cycles by splitting one physical buffer into several logically independent ones with an ordering between them.	<i>A message may only move from a lower-numbered channel to a higher one, so the dependency graph becomes acyclic by construction.</i>
6	Dimension-ordered routing breaks cycles in a mesh by forbidding a turn.	<i>X then Y: the turns that would close a cycle are simply not permitted. Cheap, and it costs path diversity, which costs throughput under adversarial traffic.</i>

The most common on-chip deadlock has nothing to do with routing. It is a read response that cannot make progress because the response buffer is full of responses waiting behind a write that cannot complete because the write channel is blocked by a request from the same master. Protocol specifications address this with ordering rules — AXI's requirement that read and write channels be independent, and that a slave must not make a read response depend on a future write — and **those rules are routinely broken by IP blocks that share one internal queue between the two channels.** If your block merges AXI's read and write paths into a single ordered structure anywhere, you have created this deadlock, and it will appear in a customer's system and not in yours.

Problem. A bridge accepts an AXI write and must issue a read to fetch the rest of a partially written cache line, then complete the write. Why is this a deadlock hazard, and what are the fixes?

Solution. It creates a dependency from the write channel to the read channel. If the read travels through the same interconnect and that interconnect is congested with writes — including this one, which is holding a slot — the read cannot be issued and the write cannot retire. The wait-for graph has a cycle. Three fixes, in increasing order of cost and decreasing order of fragility. **Reserve resources before accepting:** do not accept the write until a read slot and a line buffer are already allocated, so the bridge never holds and waits. **Use a separate virtual or physical channel** for the fetch, so the read's path cannot be blocked by writes. **Buffer the entire write** and acknowledge it immediately, converting the dependency into a local one — which costs a full line of storage per outstanding write and changes the coherence behaviour. Whichever is chosen, **the argument must be written down as an acyclicity claim about the dependency graph**, because it is not something a simulation will refute reliably: deadlocks appear only under specific congestion, and the bench that would produce it is rarely the bench that is written.

X11.4 Topology and the wire budget

Table 272. Topologies: links and worst-case hop count

Nodes	Full crossbar links	Ring: worst hops	2-D mesh: worst hops	Hypercube: worst hops	Ring links
4	6	3	2	2	2
8	28	7	—	3	4
16	120	15	6	4	8
32	496	31	—	5	16
64	2,016	63	14	6	32

The crossbar column is the reason crossbars stop at modest radix: the link count is quadratic and each link is a full-width bus. Beyond about 16 ports a hierarchy of smaller crossbars wins on area even though it adds hops.

Worked example 24. Bisection bandwidth decides, not link count

Given. A 16-node system, 128-bit links at 1 GHz. Compare a ring, a 4×4 mesh and a full crossbar under uniform random traffic, where on average half the traffic crosses the bisection.

Method. Compute the bisection bandwidth — the bandwidth across the worst cut that divides the network in half — and compare with the offered load. Bisection, not aggregate link bandwidth, is what limits uniform traffic.

Per-link bandwidth	16 GB/s
Ring: links crossing the bisection	2
Ring bisection bandwidth	32 GB/s
4×4 mesh: links crossing	4
Mesh bisection bandwidth	64 GB/s
Crossbar bisection bandwidth	128 GB/s
Offered load if each node sends 8 GB/s, half crossing	64 GB/s
Ring sufficient?	no
Mesh sufficient?	no
Crossbar sufficient?	yes

How this is got wrong. By quoting aggregate bandwidth. The ring in this example has 16 links and 256 GB/s of aggregate link bandwidth, which sounds ample and is irrelevant: uniform traffic is limited by the two links at the cut. The corollary is that **topology should be chosen from the traffic pattern**. If the real traffic is nearest-neighbour, the ring's bisection never binds and it is the right answer; if it is all-to-all, only the bisection matters. An interconnect specified without a traffic model has not been specified.

X12. Data Converters and PLLs, Worked

Very few IP blocks are purely digital at their boundary. A SerDes has an analogue front end; a sensor interface has a converter; every synchronous block has a clock that came from a PLL. A digital designer does not have to design these, but does have to *budget* for them, and budgeting requires the same arithmetic the analogue designer uses. This part supplies it.

X12.1 The converter equations, and what they leave out

SNR, ENOB and the $6.02N+1.76$ formula

	Step	Justification
1	Quantisation error is bounded by $\pm\Delta/2$ with variance $\Delta^2/12$, if it is uniform.	<i>Part X1 established this and also measured where it fails.</i>
2	A full-scale sine of peak $A = 2^{N-1}\Delta$ has power $A^2/2$.	<i>RMS of a sinusoid.</i>
3	$\text{SNR} = 10\log_{10}(A^2/2 \div \Delta^2/12) = \mathbf{6.02N + 1.76 \text{ dB}}$.	<i>Substitute and simplify. The 1.76 is $10\log_{10}(1.5)$, the sine's crest-factor advantage over a uniform signal.</i>
4	Real converters fall short; the shortfall is expressed as ENOB = (SNDR – 1.76)/6.02 .	<i>Invert the formula using the measured signal-to-noise-and-distortion ratio. ENOB is a measurement, N is a pin count, and quoting the second as if it were the first is the standard datasheet deception.</i>
5	Aperture jitter adds a noise term $\text{SNR}_{\text{jitter}} = -20\log_{10}(2\pi f_{\text{in}}\sigma_t)$.	<i>The sampled error is the signal's slew times the timing error; slew is proportional to input frequency. This term does not depend on N at all and eventually dominates every high-speed converter.</i>

Table 273. Effective bits achievable with 1 ps RMS aperture jitter, against nominal resolution and input frequency

Nominal N	Ideal SNR (dB)	ENOB at 1 MHz	at 10 MHz	at 100 MHz	at 1 GHz
8	49.92	8	8	7.97	6.86
10	61.96	10	10	9.65	7.01
12	74	12	11.9	10.3	7.02
14	86.04	14	13.3	10.3	7.02
16	98.08	15.8	13.6	10.3	7.02

Read down the last column: **at 1 GHz input, 1 ps of jitter caps the converter at about 8 bits no matter how many bits the part has**. Buying a 16-bit converter without buying a cleaner clock buys nothing.

Figure 35. The jitter wall. Every curve falls 20 dB per decade of input frequency; the only way up is a better clock.

Worked example 25. Specifying the clock for an ADC, backwards from the requirement

Given. A receiver needs 11 effective bits on a 500 MHz input. The converter's own thermal and distortion contribution is 13 ENOB.

Method. Convert the requirement to an SNR, subtract the converter's own contribution in the power domain to find the jitter budget, then invert the jitter formula.

Required SNDR	67.98 dB
Converter's own SNR	80.02 dB
Permitted jitter-noise SNR	68.26 dB
Permitted RMS aperture jitter	123 fs
Is that achievable with an on-chip PLL?	demanding — it is at the edge of a good integrated LC PLL

How this is got wrong. By subtracting decibels instead of powers. Noise contributions add in power, so budgets must be combined as $10^{-\text{SNR}/10}$ terms and only then converted back. Subtracting 11 from 13 in dB gives a meaningless number. The second error, subtler, is to forget that the *clock buffer* between the PLL and the sampler adds its own jitter, often more than the PLL, so a budget that spends the whole allowance on the PLL has already failed.

Table 274. Converter architectures and where each lives

Architecture	Resolu- tion	Speed	Latency	Cost driver
Flash	4–6 bits	Highest	1 cycle	2^N comparators — area doubles per bit
Pipelined	10–14 bits	High	$N/2$ cycles	Op-amps; inter-stage gain accuracy
SAR	8–16 bits	Moderate	N cycles	Capacitor matching; scales beautifully with process
Sigma-delta	16–24 bits	Low signal band- width	High (filter)	Oversampling ratio; digital decimation filter

Architecture	Resolution	Speed	Latency	Cost driver
Time-inter-leaved	8–12 bits	Extreme	As the sub-ADC	Mismatch between channels — gain, offset and timing skew, all needing digital calibration

Graduate · Time interleaving is where the digital team earns its place in an analogue block. Running M converters in round robin multiplies the sample rate by M and introduces three mismatches: offset, which appears as spurs at multiples of f_s/M ; gain, which appears as spurs around the signal; and timing skew, which appears as signal-dependent spurs that grow with input frequency. None is removable by better layout alone at modern speeds; all three are corrected by **digital background calibration** that estimates the mismatch from the data and applies a correction. That estimator is a piece of DSP with a convergence time, a lock detector and a failure mode, and it is specified, modelled and verified by the digital side. **A SerDes receiver's ADC is time-interleaved 32 or 64 ways, and its calibration loops are a substantial part of the digital block's area.**

X12.2 Phase-locked loops: the transfer functions that matter

Why a PLL is a lowpass for reference noise and a highpass for VCO noise

	Step	Justification
1	Open loop: $G(s) = K_{pd}F(s)K_{vco}/s$, divided by N .	Phase detector gain, loop filter, VCO as a phase integrator, feedback divider.
2	Reference to output: $N G/(1+G)$.	Standard feedback algebra. At low frequency $G \gg 1$ so this is N ; at high frequency it rolls off. Lowpass.
3	VCO noise to output: $1/(1+G)$.	The VCO's noise enters after the phase detector. At low frequency the loop suppresses it; above the bandwidth it passes. Highpass.
4	So the loop bandwidth is a crossover, not a quality setting.	Wide bandwidth tracks the reference and suppresses VCO noise; narrow bandwidth rejects reference noise and lets the VCO run free. The optimum is where the two noise densities cross, and that point is measured , not chosen by taste.
5	Total output jitter is the integral of the combined phase-noise spectrum over the band of interest.	Which is why a jitter specification without an integration band is incomplete — the same part can be quoted at 200 fs or 2 ps depending on limits.

Table 275. Integrated jitter of a 2.5 GHz PLL against loop bandwidth, with a toy noise model (reference -100 dBc/Hz flat, VCO -80 dBc/Hz at 1 MHz, $N = 20$)

Loop bandwidth (MHz)	Output phase noise at 10 kHz (dBc/Hz)	at 1 MHz (dBc/Hz)	Integrated RMS jitter 10 kHz–100 MHz (fs)
0.1	-59.87	-79.87	35204
0.5	-70.97	-77.96	22387
1	-73.01	-76.02	25070
2	-73.72	-74.69	32635
5	-73.94	-74.11	49869

Integrated numerically over the stated band. There is a minimum: too narrow and the VCO dominates, too wide and the reference multiplied by N^2 dominates. **The $20\log_{10}N$ multiplication of reference noise is the term designers forget, and it is 26 dB here.**

A PLL specification needs five numbers and is usually given two. Output frequency and jitter are not enough. The five are: output frequency range; **integrated jitter with its integration band**; spurious tone level, since a single reference spur can violate a mask that broadband jitter passes; lock time, which sets how long a power-gated block takes to become usable; and the **input reference's own phase noise**, since the PLL multiplies it by $20\log_{10}N$. A block that is specified without the fifth will work on the vendor's evaluation board with a laboratory clock source and fail in the customer's system with a crystal oscillator.

Table 276. Reference phase noise is multiplied by the divide ratio

Divide ratio N	$20\log_{10}N$ (dB)	Output noise from a -100 dBc/Hz reference	Output noise from a -130 dBc/Hz reference
2	6.021	-93.98	-124
4	12.04	-87.96	-118
10	20	-80	-110
20	26.02	-73.98	-104
50	33.98	-66.02	-96.02
100	40	-60	-90

In-band only — above the loop bandwidth the reference is filtered. This is the reason a high-speed SerDes wants a low reference multiplication, and the reason a 100 MHz reference often beats a 25 MHz one for the same output frequency.

Problem. A clock-and-data-recovery loop and a frequency-synthesis PLL are both PLLs. Why is the CDR's bandwidth chosen by a standard rather than by the designer?

Solution. Because in a CDR the loop bandwidth determines **jitter tolerance**, which is an interoperability property rather than a performance one. Jitter below the loop bandwidth is tracked by the receiver and causes no error; jitter above it is not tracked and eats the eye directly. So the receiver's bandwidth and the transmitter's permitted jitter spectrum are two halves of one specification: if each vendor chose its own bandwidth, a compliant transmitter and a compliant receiver could still fail together. Standards therefore specify a **jitter tolerance mask** — how much sinusoidal jitter the receiver must survive at each frequency — which constrains the loop bandwidth from below, and a **jitter transfer limit**, which constrains it from above so that jitter is not amplified around the loop's peaking and accumulated through a chain of repeaters. **The designer's freedom is what remains between the two masks**, and in modern standards that gap is narrow.

Problem. Why does a fractional- N synthesiser need a delta-sigma modulator, and what does it cost?

Solution. A divider divides by an integer. To reach a fractional average the divide ratio must be switched between neighbouring integers, and the *pattern* of switching determines where the resulting phase error lands in frequency. A simple periodic pattern puts it at a low frequency inside the loop bandwidth, where it appears as a **fractional spur** — a discrete tone that violates masks. A delta-sigma modulator chooses the pattern so that the quantisation error is *shaped* to high frequency, where the loop filters it. The costs are real: the shaped noise is larger in total than the unshaped noise, so the loop bandwidth must be kept below the point where the shaping rises; a higher-order modulator shapes harder but can produce idle tones if its input sits near a simple fraction, which is why implementations dither the input; and the divider must now handle a range of ratios, which complicates its design. **This is a clean example of a digital block bought to relax an analogue constraint**, which is the dominant trend in mixed-signal design and the reason the boundary keeps moving toward the digital side.

X13. Machine-Learning Hardware, Worked

Neural-network accelerators are the largest category of new IP by value, and they are also the category where the gap between a quoted peak number and delivered performance is widest. The arithmetic that closes that gap is the roofline model and its refinements, and it is worth doing carefully because it decides the architecture before a line of RTL is written.

X13.1 The roofline, computed for real layers

Arithmetic intensity and where the roof bends

	Step	Justification
1	A kernel performs W operations and moves Q bytes.	<i>Definitions.</i>
2	Arithmetic intensity $I = W/Q$, operations per byte.	<i>A property of the algorithm and the dataflow, not of the machine.</i>
3	Achievable performance = $\min(P_{\text{peak}}, I \cdot B)$, with B the memory bandwidth.	<i>You cannot compute faster than the machine, nor faster than the data arrives.</i>
4	The ridge point is at $I = P_{\text{peak}}/B$.	<i>Below it the kernel is memory bound and peak FLOPS are irrelevant.</i>
5	For a modern accelerator P_{peak}/B is in the hundreds.	<i>Which means most layers are memory bound unless the dataflow is designed to raise I — and raising I is what the whole accelerator architecture is for.</i>

Table 277. Arithmetic intensity of common layers, int8, no reuse beyond the layer

Layer	MOPs	Bytes moved (kB)	Ops per byte	Bound by (ridge = 200)
Conv 3×3, 256 → 256, 56×56	3699	2144	1685	compute
Conv 1×1, 512 → 128, 28×28	102.8	554	181.1	memory
Conv 3×3 depthwise, 512, 14×14	0	98.19	0	memory
Fully connected 4096 → 4096	33.55	16392	1.999	memory
Attention QK ^T , $d=64$, $n=1024$	1.374×10^5	1.114×10^6	120.5	memory

Computed assuming each weight and activation is read once from off-chip, which is the worst dataflow. **The point of an accelerator's on-chip memory hierarchy is to make this table wrong** by reusing data; how much it can reuse is the design.

Graduate · Depthwise convolution is the instructive row. It has excellent parameter efficiency — which is why MobileNet-style networks use it — and terrible arithmetic intensity, because each weight is used for only one input channel. On an accelerator designed around dense convolution it can run at a few per cent of peak, so a network that is 4× cheaper in operations can be *slower* in wall-clock time. **This is the clearest example in the field of why operation counts are not a performance metric**, and it is a question worth asking any vendor: not ‘what is your TOPS’ but ‘what is your utilisation on a depthwise layer’.

Figure 36. A roofline for a 100 TOPS accelerator with 500 GB/s. The ridge is at 200 ops/byte; everything to its left is a bandwidth problem wearing a compute problem's clothes.

X13.2 Dataflow: what a systolic array is actually reusing

Table 278. Dataflow taxonomy by what stays still

Dataflow	Held stationary	Reuse obtained	Weak when
Weight stationary	Weights in the PE	Each weight is used for a whole batch or feature map	Batch is 1 and the feature map is small
Output stationary	The partial sum in the PE	No partial sums move — saves the widest data	Few accumulations per output (1×1 convolutions)
Input stationary	The activation	Each activation feeds many filters	Few output channels
Row stationary	A row of the convolution in each PE	Balances all three reuse types	Complex control and mapping
No local reuse	Nothing	—	Always — it is the baseline that makes the others look good

Worked example 26. Sizing a systolic array from a bandwidth limit

Given. A 256×256 int8 multiply–accumulate array at 1 GHz, weight stationary. Off-chip bandwidth 100 GB/s.

Method. Compute the peak rate, then compute the byte rate the array would demand with no reuse, then find the reuse factor required to keep it fed.

MACs per cycle	65,536
Peak operations	131.1 TOPS
Operands needed per cycle with no reuse	131,072 bytes
Byte rate demanded	131.1 TB/s
Available	0.1 TB/s
Reuse factor required	1311×
On-chip SRAM to achieve it (order)	megabytes

How this is got wrong. By quoting the TOPS figure and stopping. The array is 131 TOPS and the memory system can feed it 1/1300th of what it wants. Every architectural feature of a real accelerator — the weight buffer, the activation buffer, the tiling, the fusion of adjacent layers — exists to close that factor of 1300, and **the accelerator is really a memory system with multipliers attached**. A design house pitching an accelerator should lead with the memory hierarchy, because that is what a knowledgeable buyer will ask about first.

X13.3 Quantisation: where the bits actually go

Table 279. Measured SQNR of a 512×512 int matrix product, per-tensor vs. per-channel weight scaling

Bits	Per-tensor SQNR (dB)	Per-channel SQNR (dB)	Gain (dB)	Weight storage (kB)
8	39.08	41.29	2.21	256
6	26.8	29.15	2.35	192
4	13.8	16.26	2.47	128
3	6.414	9.003	2.59	96
2	-0.08753	0.6042	0.692	64

Gaussian weights and post-ReLU activations, seed 21. **Per-channel scaling is nearly free in hardware** — one extra multiply per output channel, not per MAC — and buys several dB, which at low bit widths is the difference between a usable and an unusable network.

The outlier problem, and why it changed transformer accelerators. The table above uses Gaussian weights, for which max-based scaling is reasonable. Real transformer activations are not Gaussian: a few channels carry values tens of times larger than the rest, and a per-tensor scale chosen to contain them leaves the remaining channels occupying two or three bits. The measured consequence is that naive int8 quantisation of a large language model loses far more accuracy than the same procedure applied to a convolutional network, and the remedies — per-channel and per-group scales, keeping outlier channels in higher precision, or migrating the scale between activations and weights — all cost hardware that a convolution-era accelerator does not have. **An accelerator's quantisation support is a workload-specific design decision, not a generic feature.**

Problem. Why does int8 inference usually retain accuracy while int8 training does not?

Solution. Because the two use the numbers differently. Inference computes a forward pass whose outputs pass through nonlinearities that are insensitive to small perturbations, and errors do not accumulate across iterations — each inference is independent. Training computes gradients, which are (a) small differences of large numbers, so relative precision matters far more, (b) accumulated over many steps, so bias accumulates exactly as Part X1's truncating accumulator did, and (c) spread over an enormous dynamic range, because gradients of different layers differ by orders of magnitude. The practical resolution is the asymmetric one: **low-precision multiplies with higher-precision accumulation and master weights**, plus loss scaling to move small gradients out of the denormal region. bfloat16 exists for exactly the (c) reason — it sacrifices mantissa, which inference cares about, to keep exponent range, which training cares about.

Problem. A customer wants your accelerator to be ‘future proof’. What can you honestly offer?

Solution. Not architectural coverage of models that do not exist. What you can offer is specific and worth more than a vague claim: **a programmable dataflow** rather than a fixed one, so a new layer shape maps at some efficiency rather than not at all; **a well-specified fallback path** to a host or a DSP for operators the array cannot do, with measured numbers for that path so the customer can compute the Amdahl penalty themselves; **a compiler that is open enough to extend**, since in practice the compiler ages faster than the silicon; and **measured utilisation on a set of named, versioned models**, so the customer can extrapolate from evidence rather than from adjectives. **Offering the measurement methodology is itself a differentiator**: most data-sheets in this field quote one peak number and one optimistic model, and a buyer who has been burned once recognises the difference immediately.

X14. Physical Design as the RTL Designer Sees It

A soft-IP vendor does not run place-and-route on the customer's chip, but the vendor's RTL determines whether that run succeeds. This part covers the physical facts that propagate back into RTL decisions, with the arithmetic that makes them checkable.

X14.1 Wire delay does not scale, and that changes architecture

Why a long wire gets relatively slower every generation

	Step	Justification
1	A wire's distributed RC delay is $0.38rcL^2$ for resistance r and capacitance c per unit length.	<i>Elmore delay of a distributed line. Quadratic in length — the single most important fact in this chapter.</i>
2	Scaling reduces wire cross-section, so r rises roughly as $1/S^2$ while c stays roughly constant.	<i>Thinner and narrower conductor, same dielectric spacing ratio.</i>
3	A wire of <i>fixed physical length</i> therefore gets slower as the process shrinks.	<i>While gates get faster. The ratio moves against the wire every generation.</i>
4	Buffering breaks the quadratic: k equal segments give $k \cdot (L/k)^2 = L^2/k$ plus k buffer delays.	<i>Optimise over k and the delay becomes linear in L.</i>
5	So a long wire costs area and power, and it costs a fixed delay per millimetre that no amount of cleverness removes.	<i>Which makes distance an architectural quantity. A design whose blocks must exchange data every cycle across a chip is not implementable at high frequency, however good the RTL.</i>

Table 280. Wire delay with and without optimal buffering (250 Ω /mm, 200 fF/mm, 20 ps buffers)

Length (mm)	Unbuffered delay (ps)	Buffers	Buffered delay (ps)	ps per mm	Speed-up
0.1	0.19	1	20.19	201.9	0.00941
0.5	4.75	1	24.75	49.5	0.192
1	19	2	49.5	49.5	0.384
2	76	5	115.2	57.6	0.66
5	475	12	279.6	55.92	1.7
10	1900	25	576	57.6	3.3

The constants are indicative of an intermediate metal layer in a mature node and are not from a specific PDK. **The shape is what matters:** the unbuffered column is quadratic, the buffered column is linear, and the per-millimetre figure is roughly constant — which is why architects budget in millimetres.

Worked example 27. How far can a signal travel in one cycle?

Given. A 1 GHz design in the process above. Allow half the period for wire and half for logic and flop overhead.

Method. Divide the available wire time by the per-millimetre delay from the table.

Period	1,000 ps
Wire budget	500 ps
Delay per mm, buffered	57.6 ps/mm
Reachable distance in one cycle	8.68 mm
At 3 GHz	2.89 mm
Typical die edge	10 mm

How this is got wrong. By assuming any module can talk to any module in one cycle. At 3 GHz a signal crosses a fraction of a large die per cycle, so a chip-spanning bus is physically impossible at that frequency and the architecture must be pipelined, hierarchical, or both. **This is the physical origin of networks-on-chip:** not a preference for packets, but the observation that a global broadcast wire no longer exists. For an IP vendor the practical consequence is to keep the block's internal critical paths local and to **register every boundary signal**, so the customer's floorplanner has somewhere to put the pipeline stages the distance demands.

X14.2 What synthesis can and cannot fix

Table 281. Where a problem must be solved

Problem	Can synthesis fix it?	Who must
Slow gate on the critical path	Yes — upsizing, Vt swap	The tool
Badly structured arithmetic	Usually — it re-implements operators	The tool, if the RTL uses + and * rather than hand-built structures
Too many logic levels between flops	No	The RTL — add a pipeline stage
High fan-out net	Partly — it buffers	The RTL, if the fan-out is architectural (a global enable)
Congestion from a crossbar	No	The architecture — reduce the radix or add a stage
Clock domain crossing	No — and it may <i>break</i> one by optimising away a synchroniser	The RTL, plus constraints marking the crossing
Latch inferred from an incomplete case	It will report it	The RTL — always
Multi-cycle path	No	The constraint file, with justification

Synthesis can delete your synchroniser. The two flops of a synchroniser are functionally redundant to a tool that believes the input is a normal signal: it may merge them, retime through them, or move one across a boundary, any of which destroys the resolution time the MTBF calculation of Part X3 depends on. The defences are to mark the flops with a synthesis attribute that forbids merging and retiming, to place them in a module the tool is told not to ungroup, and **to check the gate-level netlist that they are still there** — a check that can be automated and belongs in the sign-off list. A design that relies on the tool's good behaviour here has an MTBF nobody has verified.

X14.3 Utilisation, congestion and the numbers that predict trouble

Table 282. Relative routing difficulty against placement utilisation (heuristic model)

Utilisation (%)	Relative difficulty	vs. 50 %	Practical verdict
50	2.828	1	comfortable
60	3.953	1.4	comfortable
70	6.086	2.15	comfortable
75	8	2.83	tight
80	11.18	3.95	tight
85	17.21	6.09	expect congestion
90	31.62	11.2	expect congestion

The model is a heuristic, not a PDK number: difficulty grows as $(1-u)^{-1.5}$. **Its only job is to make the shape visible** — the cost is mild to 70 % and then rises very fast, which is why floorplans target 65–75 % and why ‘we will just raise utilisation’ is rarely the answer to an area problem.

Graduate · Congestion is caused by pin density and connectivity, not by cell area, and this distinction decides what an RTL designer can do about it. A block that is 60 % utilised can be unroutable if its cells are small and richly connected — a crossbar, a large multiplexer tree, a register file read network — because the routing demand per unit area is set by nets crossing a boundary, not by transistors under it. The RTL-level remedies are therefore about *connectivity*: reduce the radix of a switch and add a stage; replace a fully-connected structure with a hierarchical one; move a wide mux into a memory where the decoder is dense and local; and **avoid the one-hot broadcast structures that look cheap in gate count and are expensive in tracks**. An area report will not show any of this; a congestion map will.

Problem. Your block meets timing standalone at 800 MHz but the customer reports it fails at 600 MHz in their chip. Name four causes, in the order you would check them.

Solution. 1. Different constraints. Your standalone run may have used ideal clocks, no input/output delay, or a different corner set. Ask for their SDC and compare it with yours line by line; this is the cause more often than the other three together. **2. Boundary paths.** Standalone runs frequently constrain inputs and outputs generously; in the chip your block's inputs arrive late and its outputs must arrive early. This is why registering every boundary is worth the latency — it makes your timing independent of their floorplan. **3. Physical context.** In their chip your block may be stretched around a macro, sit far from its clock source, or share power rails with a noisy neighbour, all of which add delay your standalone run did not model. **4. A different library or corner.** Same process, different vendor library or different Vt mix, and your critical path is no longer their critical path. **The general lesson for a vendor is to ship the constraints and the conditions with the frequency claim;** a frequency without them is not a specification, and this exact conversation is why.

Problem. Why do IP vendors quote area in gate equivalents rather than square micrometres?

Solution. Because square micrometres are meaningless without naming the process, the library and the utilisation, and a vendor who names all three has effectively told a competitor which foundry and library they used. A gate equivalent — conventionally the area of a two-input NAND in the same library — is a ratio, so it survives the translation between processes approximately, and it lets a customer scale to their own library by multiplying by their NAND area. **The approximation is worse than it looks,** because the ratio of flop area to NAND area and of SRAM bit-cell area to NAND area both vary between libraries, so a flop-heavy block converts less accurately than a logic-heavy one. The honest datasheet therefore gives **gate equivalents, flop count and memory bits separately**, which lets the customer do the conversion properly, and costs the vendor nothing.

X15. Hardware Security, Worked

Security is where a plausible-looking design is most often wrong, because the adversary is not a random input but a person who reads your datasheet. This part covers the parts of hardware security that are arithmetic — how many traces an attack needs, how much entropy a source really has, how long a key survives — because those are the parts a designer can actually bound.

X15.1 Side channels: the attack is a statistics problem

Why correlation power analysis works, and how many traces it needs

	Step	Justification
1	Dynamic power depends on the number of bits that switch, which depends on the data being processed.	Part X7's $\alpha CV^2 f$: α is data dependent.
2	Choose an intermediate value $v = f(\text{plaintext}, \text{key guess})$ that the device computes, e.g. an AES S-box output.	It must depend on a small part of the key so the guesses can be enumerated.
3	Predict the leakage as a model, commonly the Hamming weight of v .	A crude model that works because switching count correlates with it.
4	Correlate the predicted leakage with the measured power across many traces, for every key guess.	The correct guess correlates; the others do not, because their predicted values are effectively random with respect to the device's actual computation.
5	The number of traces needed is $n \approx 3 + 8(Z_\alpha / \ln((1+p)/(1-p)))^2$.	Fisher's z-transform of the correlation coefficient. Quadratic in $1/p$, which is why reducing the signal by a factor of ten costs the attacker a factor of a hundred in traces.

Table 283. Traces needed for a correlation attack against the leakage correlation ρ (99.99 % confidence)

ρ	Traces needed	Relative to $\rho = 0.5$	Acquisition hours at 1 ms per trace
0.5	109	1	3.03×10^{-5}
0.2	781	7.167	2.17×10^{-4}
0.1	3,181	29.18	8.84×10^{-4}
0.05	12,781	117.2	0.00355
0.02	79,981	733.4	0.0222
0.01	319,981	2934	0.0889
0.005	1,279,981	11737	0.356

Computed from the z-transform expression. **Read the last column as the security margin:** an unprotected implementation falls in minutes, and each factor of ten in leakage reduction costs the attacker a factor of a hundred in time. A countermeasure does not have to be perfect, it has to move this column past the value of the key.

Table 284. Countermeasures, what each does to ρ , and what it costs

Counter-measure	Mechanism	Effect	Cost
Masking	Split each secret into shares whose individual distributions are independent of the secret	Removes first-order leakage entirely; the attacker must combine $d+1$ points, and the trace count grows exponentially in d	2–4× area and a source of fresh randomness every cycle

Counter-measure	Mechanism	Effect	Cost
Hiding (dual rail, WDDL)	Make switching activity constant	Reduces p , does not remove it — routing imbalance leaks	2× area, careful layout
Shuffling	Randomise the order of independent operations	Divides p by roughly the number of permuted slots	Cheap; combines well with masking
Noise injection	Add uncorrelated activity	Reduces p by the amplitude ratio	Power; attacker averages it away — buys time, not security
Frequency randomisation	Jitter the clock	Misaligns traces; defeated by alignment preprocessing	Cheap and weak on its own
Key refresh	Limit the traces available per key	Caps the attack directly	Protocol support

A masked implementation that is not verified at the gate level is usually not masked. Masking is a property of the *computation*, and synthesis optimises computations. If the tool finds that two shares are combined in a common subexpression — which is exactly the kind of optimisation it is good at — the shares meet in one gate and the first-order leakage returns, while the RTL still looks masked. There is a second, subtler failure: even without optimisation, a **glitch** in combinational logic can momentarily present a function of both shares, which is why threshold implementations are designed to be glitch-resistant by construction rather than merely share-correct. **The verification here is formal leakage analysis on the netlist**, not inspection of the source.

X15.2 Entropy: counting what a random number generator really has

Worked example 28. A ring-oscillator TRNG, entropy per bit

Given. Two free-running ring oscillators, one sampled by the other. Jitter accumulates over the sampling interval; the accumulated timing uncertainty is $\sigma = 12$ ps and the sampled oscillator's period is $T = 400$ ps.

Method. The min-entropy of the sampled bit depends on how much of a period the uncertainty spans. A standard stochastic-model estimate is $H \approx 1 - (4/\pi^2)e^{-4\pi^2\sigma^2/T^2}$, which goes to 1 when the jitter covers a period and to 0 when it is small.

σ/T	0.03
Exponent argument	0.03553
Estimated entropy per raw bit	0.6089
Raw bits needed per full-entropy bit	1.642
If σ falls to 3 ps (a quieter supply): entropy	0.5956
Raw bits per full-entropy bit then	1.679

How this is got wrong. By testing the output of the conditioner instead of the source. A cryptographic hash applied to a biased source produces output that passes every statistical test — that is what a hash does — while containing only as much entropy as went in. **The test must be applied to the raw source**, with an online health test that keeps checking it in the field, because the quantity being relied on (σ) depends on supply noise, temperature and ageing, and an attacker with access to the supply can reduce it deliberately. The second row from the bottom is that attack expressed as arithmetic.

Graduate • Why the standards insist on min-entropy rather than Shannon entropy. Shannon entropy is an average; an adversary guesses the most likely value. A source that emits 0 with probability 0.9 has Shannon entropy 0.47 bits and min-entropy $-\log_2(0.9) = 0.15$ bits, and the second number is the one that bounds an attacker's success. For a key of k bits assembled

from such a source, the attacker's work is 2 raised to the total *min*-entropy, not the total Shannon entropy — a factor of $2^{0.32}$ per bit, which over 256 bits is a factor of 10^{24} . **Using the wrong entropy measure is not conservative rounding, it is a wrong security claim.**

X15.3 Fault attacks and the cost of detection

Table 285. Fault-attack countermeasures

Countermeasure	Mechanism	Catches	Overhead
None	—	0 %	0 %
Parity on registers	1 bit per word	single-bit faults	3–12 %
Duplication	Run twice, compare	any single fault	>100 %
Time redundancy	Run twice in sequence	transient faults only	0 % area, 100 % time
Inverse check	Decrypt the ciphertext and compare	any fault in the datapath	~100 % time
Infective computation	Spread the fault so the output is useless	prevents exploitation rather than detecting	moderate

*The classic differential fault attack on RSA-CRT recovers the private key from **one** faulty signature, which is why the inverse check — verify the signature before releasing it — is standard there despite its cost. **When one fault is enough, probabilistic countermeasures are not.***

Problem. A customer asks for a ‘secure’ AES block. What do you ask them before quoting?

Solution. Four questions, because ‘secure’ alone does not specify anything. **What is the attacker's physical access?** A block in a server that an attacker cannot touch needs no side-channel countermeasures; a smart card that the attacker owns needs every one of them, and the area difference is a factor of three. **How many operations per key?** This bounds the traces available and therefore the required leakage reduction directly, via the table in X15.1. **What certification is required?** Common Criteria or FIPS levels prescribe specific countermeasures and specific evidence, and the evidence costs more than the design. **What is the throughput and latency requirement?** Masking costs randomness per cycle, and a design that must run at line rate may not be able to afford the randomness generation. **A quote given without these answers will be wrong by a large factor in one direction or the other,** and a vendor who asks them is demonstrating exactly the competence being bought.

Problem. Why is a hardware root of trust harder than storing a key in fuses?

Solution. Because the key is the easy part. A root of trust must establish, at every boot, that the first code to run is the code the owner intended — which requires immutable boot code, a verified signature chain, and protection of the verification itself from the fault and side-channel attacks above. It must survive the states nobody designs for: reset during an update, a power glitch mid-verification, a debug interface left enabled. It needs a way to revoke a compromised key and to roll forward a version counter that cannot be rolled back, which means monotonic storage, which means more fuses and a policy for them. And it must do all this while remaining **debuggable in the field by the legitimate owner**, which is the requirement that quietly reopens every door the rest closed. **The key in fuses is perhaps five per cent of the work;** the rest is the state machine around it, and that state machine is where the published attacks land.

X16. Reliability, Yield and Functional Safety, Worked

Three quantities decide whether a chip can be sold into an automotive, industrial or medical market, and all three are arithmetic: the fraction of dies that work, the rate at which working dies stop working, and the fraction of dangerous failures that are detected. A design house that can compute them can quote for markets that pay considerably more than consumer.

X16.1 Yield: the model and its parameter

From defect density to die yield

	Step	Justification
1	Defects fall on the wafer at an average density D_0 per unit area.	<i>Empirical; the foundry supplies it and it falls over a process's life.</i>
2	If defects were Poisson and independent, yield would be e^{-AD_0} .	<i>Probability of zero defects in area A.</i>
3	They are not independent — defects cluster — so Poisson is pessimistic for large dies.	<i>Clustering means some wafers are bad and others clean, which raises the average yield of the clean ones.</i>
4	The negative-binomial (Murphy/Seeds) model adds a clustering parameter α : $Y = (1 + AD_0/\alpha)^{-\alpha}$.	<i>$\alpha \approx 2-5$ in practice; $\alpha \rightarrow \infty$ recovers Poisson.</i>
5	Yield falls superlinearly with die area , and total good dies per wafer falls faster still.	<i>Which is the whole argument for chiplets, and the reason a large monolithic die is a business decision as much as a technical one.</i>

Table 286. Yield against die area at $D_0 = 0.10 / \text{cm}^2$, $\alpha = 3$, 300 mm wafer

Die area (mm ²)	Poisson yield	Negative-binomial yield	Gross die/wafer	Good die/wafer	Relative cost per good die
10	0.99	0.9901	6,503	6,438	1.01
25	0.9753	0.9754	2,601	2,537	1.025
50	0.9512	0.9516	1,300	1,237	1.051
100	0.9048	0.9063	650	589	1.103
200	0.8187	0.824	325	267	1.214
400	0.6703	0.687	162	111	1.456
800	0.4493	0.4921	81	39	2.032

The last column is cost per working die relative to a perfect-yield part, holding wafer cost fixed. An 800 mm² die costs far more than eighty times a 10 mm² one, which is the economics that produced chiplets.

Figure 37. The two models diverge exactly where the decision is hard. Using Poisson for a large die understates yield and can kill a viable product; using it for a small die makes no difference.

Worked example 29. Redundancy in a memory, and when it pays

Given. A 16 Mbit SRAM occupying 20 mm². Adding 2 % area of spare rows and columns with laser or fuse repair can repair any single defect in a row or column.

Method. Compare the yield of the memory with and without repair, using the negative-binomial model, and weigh the 2 % area against the yield gain.

Memory area	20 mm ²
Yield without repair	0.9803
With 2 % area added	0.9799
Defects repairable (assume 80 % are single row/column)	80 %
Effective yield with repair	0.996
Gain	0.016
Area cost	2 %

How this is got wrong. By applying the same reasoning to random logic. Memory repair works because memory is regular: a spare row is interchangeable with any row, so one spare covers a whole class of defects. Random logic has no such structure, and the equivalent — triple modular redundancy — costs over 200 % rather than 2 %. **This asymmetry is why yield-enhancement effort concentrates on memory**, and why a design that is 60 % memory by area has a very different yield story from one that is 60 % logic. It is worth knowing which yours is.

X16.2 Wear-out: the four mechanisms and their accelerations

Table 287. Why parts that passed test fail later

Mechanism	Physics	Accelerated by	Design response
Elec-tromigration	Momentum transfer from electrons moves metal atoms; voids open	Current density and temperature	Width rules per current; the tool checks them if told the currents

Mechanism	Physics	Accelerated by	Design response
NBTI / PBTI	Interface traps shift the threshold voltage under bias	Voltage, temperature, and duty cycle	Guardband; some recovery when the stress is removed, which makes measurement subtle
TDDDB	Gate oxide accumulates damage until it conducts	Electric field, exponentially	Voltage limits; thicker oxide for I/O
Hot carrier injection	Energetic carriers embed in the oxide	Switching activity and short channels	Slew limits; affects high-activity nodes such as clocks
Soft errors	Ionising particle upsets a node	Altitude, cell size, node capacitance	ECC and scrubbing — Part X10

Table 288. Arrhenius acceleration relative to 55 °C, $E_a = 0.7$ eV

Junction temperature (°C)	Acceleration factor	Field years equivalent to 10 test hours	Field years equivalent to 1000 test hours
55	1	10	1000
85	7.953	1.257	125.7
105	26.4	0.3788	37.88
125	77.66	0.1288	12.88
150	259.2	0.03857	3.857

*This is how a fifteen-year automotive lifetime is qualified in weeks: stress at 150 °C and multiply. **The activation energy is per mechanism and is the parameter the whole extrapolation rests on;** quoting a lifetime without naming E_a and the mechanism it was measured for is not a lifetime claim.*

Acceleration factors multiply the error in E_a enormously. At 150 °C the factor above is roughly 170; had E_a been 0.5 eV instead of 0.7, it would be about 40. So a 10 % uncertainty in an exponent's parameter becomes a factor of four in the predicted lifetime, and the direction of the error is not conservative — assuming a high E_a makes the test look more severe than it was. **This is the same structural hazard as the metastability τ of Part X3:** a quantity inside an exponent, measured with modest precision, on which a large claim rests. Both deserve the same treatment: use the worst plausible value, and say which value you used.

X16.3 Functional safety: what ISO 26262 actually asks for

Table 289. The safety metrics, in plain arithmetic

Metric	Definition	ASIL B	ASIL D
SPFM	Fraction of single-point faults that are safe or detected	$\geq 90\%$	$\geq 99\%$
LFM	Fraction of latent multi-point faults detected	$\geq 60\%$	$\geq 90\%$
PMHF	Probabilistic metric for random hardware failures	< 100 FIT	< 10 FIT
FMEDA	The document that computes all three, gate by gate	Required	Required

Worked example 30. What a 99 % SPFM target means for a block

Given. A block with 500 000 gates and a base failure rate of 10 FIT for the whole block. ASIL D requires $\text{SPFM} \geq 99\%$.

Method. Compute the undetected fault rate the target permits, and then ask what fraction of the design must be covered by a safety mechanism to reach it.

Block failure rate	10 FIT
Permitted undetected single-point rate	0.1 FIT
Fraction of faults needing detection	99 %
Gates that must be covered (if faults are uniform)	495,000
Typical coverage of parity on registers	60–80 %
Typical coverage of duplication and compare	> 99 %
Area cost to reach ASIL D on the datapath	duplication — over 100 %

How this is got wrong. By assuming safety is a verification activity. It is an architecture activity: 99 % coverage is not reachable by testing harder, it is reachable by building detection into the design, and detection costs area that must be budgeted at the start. The usual structure is a **mixed** one — duplication on the control path, where it is small and a fault is dangerous; ECC or parity on memories, where the regularity makes it cheap; and end-to-end checks such as a CRC over a datapath, where a single check covers a great deal of logic. **A safety manual naming those mechanisms, with the coverage claimed for each, is a deliverable a customer pays for.**

Problem. Why is a ‘latent’ fault treated separately, and why does it need periodic testing?

Solution. A latent fault is one in a *safety mechanism* rather than in the function: the comparator that would detect a duplication mismatch has itself failed stuck at ‘equal’. On its own it is harmless — the function still works — which is exactly why it is dangerous: nothing reveals it, so it accumulates, and when a real fault eventually occurs the detection that was counted on is absent. The metric that bounds this is LFM, and the mechanism that serves it is a **periodic self-test**: at start-up and at intervals during operation, deliberately inject a fault and confirm the detector fires. **This is the same argument as the verification agent's self-check in Part Y4 and as this repository's whole rule about checking the checker** — a detector that is never exercised is not known to work, and in a safety context that is not a style preference but a numbered requirement with a quantitative target.

X17. Reading the Current Literature

A textbook that stops at settled material leaves the reader unable to read this year's proceedings. This part covers the directions that a designer entering the field now will meet, treated the way the rest of the book treats everything: by the arithmetic that makes each one attractive and the arithmetic that limits it. No performance claim is attributed to a specific paper here, because this repository's rule is that a citation carries a confidence level and an unread paper cannot carry a high one.

X17.1 Chiplets: the arithmetic that made them inevitable

Part X16 computed that yield falls superlinearly with die area. Chiplets exploit that directly, and the trade is entirely quantitative.

Table 290. Splitting 600 mm² of silicon into n chiplets, yield only

Chiplets	Area each (mm²)	Die yield	All- n -good yield	Relative silicon cost	Interfaces to design
1	600	0.5787	0.5787	1.728	0
2	300	0.7513	0.5645	1.772	1
4	150	0.8638	0.5568	1.796	6
8	75	0.9286	0.5529	1.809	28

The fourth column assumes every chiplet must be good, which is the pessimistic case; known-good-die testing before assembly is what makes the scheme work at all, and its cost is the missing term. *The gain is real and the last column is why it is not free.*

Worked example 31. What a die-to-die link costs, and why it decides the partition

Given. Two chiplets exchanging 1 TB/s. A die-to-die interface achieves roughly 1 pJ/bit; an on-die wire of the same length costs roughly 0.05 pJ/bit.

Method. Compute the power of the link and compare with a monolithic implementation. The number decides where the partition can be drawn.

Bits per second	8.00×10 ¹²
Die-to-die power at 1 pJ/bit	8 W
On-die equivalent at 0.05 pJ/bit	0.4 W
Penalty	7.6 W
As a fraction of a 300 W package	2.53 %
Bandwidth affordable in a 15 W budget	1.88 TB/s

How this is got wrong. By partitioning on functional boundaries instead of on bandwidth. The correct cut is the one with the least traffic across it, which is frequently *not* the tidiest functional boundary: splitting compute from memory looks natural and puts the highest-bandwidth interface across the cut, while splitting compute from I/O puts a much lower-bandwidth interface there. **Draw the traffic graph before drawing the partition**, exactly as Part X11's bisection argument requires, and note that the answer changes with the workload — which is why chiplet partitions are argued about for months.

X17.2 Near- and in-memory computing

Why moving computation to the data is attractive, and what bounds it

	Step	Justification
1	Part X13 measured arithmetic intensity: most layers are memory bound.	<i>So the machine spends its energy on movement, not arithmetic.</i>
2	Reading a 64-bit word from DRAM costs on the order of 100× the energy of a 64-bit add.	<i>The ratio varies with process and distance; the order of magnitude is the robust part.</i>
3	If the computation happens where the data is, that ratio is avoided for whatever it can do there.	<i>The gain is bounded by the fraction of work that can move, which is Amdahl's law applied to data movement rather than to time.</i>
4	Analogue in-memory computing performs the multiply–accumulate in the array itself, using conductance as the weight.	<i>One column sums currents; the addition is free and the multiply is Ohm's law.</i>
5	Its limits are precision, variability and the converters.	<i>The ADC at the bottom of each column frequently dominates area and power, which returns the design to Part X12's converter arithmetic. A technique that removes one bottleneck by creating another has to be evaluated on the sum.</i>

Table 291. A crude accounting for an analogue in-memory column: the converter dominates as precision rises (relative energy units)

Output bits	Array MAC energy	Column ADC energy	ADC share of the column (%)	Levels to resolve
2	0.02	0.5	96.2	4
4	0.02	2	99	16
6	0.02	8	99.8	64
8	0.02	32	99.9	256

*The model is illustrative, not measured, and is included to show the shape of the constraint rather than a value. **The shape is the point:** analogue in-memory computing is attractive at low output precision and loses its advantage as precision rises, which is why the published work concentrates on heavily quantised inference.*

Judge any in-memory result on the complete system, including the converters, the peripheral circuits and the data marshalling. An array-only energy figure is the analogue equivalent of a TOPS number: true, and about a part of the system that was never the bottleneck. The questions that separate a result from a product are: what precision at the output, what does the ADC cost, how is a weight updated and how often, what happens to accuracy over temperature and drift, and what fraction of a real network maps onto the array at all. **Each of those is a question this book has asked about a conventional block somewhere, which is the point: the discipline transfers.**

X17.3 Machine learning applied to the design flow itself

Table 292. Where learning is used in EDA, and what the oracle is

Application	What is learned	The oracle	Why it can work
Placement and floorplanning	A policy for placing macros	The downstream tool's own metrics	The reward is computable, if slowly — a real oracle exists

Application	What is learned	The oracle	Why it can work
Routing congestion prediction	A map from placement to congestion	The router's result	Plentiful labelled data from past runs
Timing prediction before routing	Post-route delay from pre-route features	The signoff tool	Saves iterations rather than replacing signoff
Parameter tuning	Good tool settings for a design	The tool's output	The highest-return and least glamorous application
RTL generation from natural language	Code	Nothing, unless you supply one	This is the case that differs in kind, not degree
Testbench and assertion generation	Properties and stimulus	Coverage, mutation score	An oracle exists and is measurable

Graduate · **The organising question for every row is: what verifies the output?** Where a slow but trustworthy oracle exists — the router, the timing signoff tool, a golden model — learning is search, and search with a good oracle is reliable and improves with compute. Where no oracle exists, the output must be read by a human, and the failure mode is code that looks correct, which is the most expensive kind. Part Y4's agent is built on exactly this distinction and is worth re-reading in this light: it searches a small space against a strong oracle and rejects candidates that pass only the data they were fitted to. **The strategic conclusion for a design house is that investment in golden models and checkers appreciates as generation improves**, because they are what converts an unreliable generator into a reliable one, and they are what a competitor who has only a generator cannot borrow.

Problem. A tool vendor claims their learned placer improves timing by 10 %. What do you ask?

Solution. **Against what baseline, tuned how hard?** A learned placer compared against a default-configured conventional flow is compared against a strawman; a human expert spends days on tool settings, and the comparison must include that effort or exclude it from both sides. **On how many designs, and were they in the training set?** Improvement on designs resembling the training distribution is the expected result and says nothing about yours. **What is the variance?** Placement is stochastic; a 10 % mean improvement with a 15 % spread across seeds is not an improvement you can schedule around. **What does it cost in runtime and in setup?** A placer that needs a week of fine-tuning per design is a service, not a tool. **And what happens when it fails?** A conventional flow degrades predictably; a learned one may produce a result that is fine on the metric it optimised and bad on one it did not see. These are the same questions Part Y6 asks of any paper, which is the intended lesson: **the reading discipline does not change because the subject is fashionable.**

Problem. Your customer asks whether your IP is 'AI-generated'. How do you answer?

Solution. Directly, because the question behind it is about provenance and liability rather than about tooling. Say what tools were used and for what; say what verification the output passed, which is the part that actually bounds the risk; and say what you can warrant about the origin of the code — that it is not derived from licensed or copyleft sources, and that you can produce a per-file record. **A customer's real concern is that they will inherit a legal problem or an unverified block**, and both are answerable with evidence you should have anyway. Evasion is the worst answer available: it converts a procurement question into a trust question, and Part Y5's argument about the known-issue list applies exactly — the supplier who volunteers the uncomfortable detail is the one who gets called next time.

X18. Performance Modelling: Queues, Bursts and Tails

Most hardware performance questions are queueing questions in disguise: how deep must this FIFO be, how long will this request wait, what happens when two masters are busy at once. The answers are available in closed form for the simple cases and by simulation for the rest, and having both is what lets a designer say ‘sixteen entries’ with a reason attached.

X18.1 Little's law, which is almost too simple to be useful and is not

Little's law and its three uses

	Step	Justification
1	In any stable system, $L = \lambda W$: average number in the system equals arrival rate times average time in the system.	<i>It requires only stability — no distributional assumption whatever, which is why it is the most portable result in the subject.</i>
2	Use 1: from occupancy and rate, get latency.	<i>Measure the average FIFO occupancy and the throughput, and the latency comes out without instrumenting it.</i>
3	Use 2: from rate and latency, get the buffer needed.	<i>This is the bandwidth–delay product</i> , which Parts X11, Y2 and Y3 each derived separately. They are the same theorem.
4	Use 3: as a consistency check on a simulation.	<i>If measured L, λ and W do not satisfy it, the measurement is wrong — an independent cross-check of exactly the kind Part Y6 insists on, available free.</i>

X18.2 Utilisation and the tail

Table 293. Queue length against utilisation: exponential service (M/M/1) and deterministic service (M/D/1)

Utilisation ρ	Mean queue, M/M/1	Mean queue, M/D/1	Mean time in system (service units)	Depth for 1 % overflow, M/M/1
0.3	0.4286	0.06429	1.429	4
0.5	1	0.25	2	7
0.7	2.333	0.8167	3.333	13
0.8	4	1.6	5	21
0.9	9	4.05	10	44
0.95	19	9.025	20	90
0.99	99	49	100	459

*Deterministic service halves the queue, which is the quantitative reason fixed-size flits and fixed-latency pipelines are preferred in hardware: **re-mov-ing service-time variance is worth as much as halving the load.***

Figure 38. Both curves have a pole at $\rho = 1$. A design that targets 90 % utilisation is targeting the steep part, and small errors in the load estimate become large errors in the buffer requirement.

Graduate · Why hardware designers can be more aggressive about utilisation than the curve suggests, and where that reasoning fails. The classical curves assume Poisson arrivals, which model independent users. On-chip traffic is frequently *self-limited*: a master with four outstanding transactions cannot offer more than four, so the arrival process is closed rather than open and the queue cannot blow up — the right model is a closed network, and utilisation near one is achievable. The reasoning fails exactly when the traffic becomes open: a DMA engine with deep outstanding support, several masters that do not coordinate, or a packet interface fed from outside the chip. **Ask whether the source can be throttled by the queue itself;** if it can, be aggressive, and if it cannot, respect the pole.

Table 294. Measured drop rate of a FIFO against depth, bursty arrivals (8-cycle bursts at 1/cycle, 20 % of slots start a burst, service one every 2 cycles)

Depth	Arrivals	Drops	Drop fraction	Peak occupancy reached
1	39,192	15,642	0.399	1
2	39,192	11,688	0.298	2
4	39,192	3,780	0.0964	4
8	39,192	852	0.0217	8
16	39,192	72	0.00184	16
32	39,192	0	0	28

Simulated with seed 37. The same arrival trace is replayed at every depth, so the arrivals column is identical by construction — only the buffer changes. The average offered load is 0.196 items per cycle against a service rate of 0.5, so the system is **stable on average and still drops at small depths** — because the burst arrives faster than the service can drain it. The depth at which drops stop is set by the burst, not by the average.

Worked example 32. Sizing a FIFO from a burst specification rather than an average

Given. A source delivers a 64-byte burst at one byte per cycle, then idles for at least 192 cycles. The consumer drains at one byte every 2 cycles.

Method. Compute the accumulation during the burst and the drain afterwards; the peak occupancy is the answer, and it depends only on the burst, not on the average.

Burst length	64 cycles
Arrival during burst	64 bytes
Drain during burst	32 bytes
Peak occupancy	32 bytes
Average arrival rate	0.25 B/cycle
Average service rate	0.5 B/cycle
Utilisation	0.5
Depth an average-based calculation would suggest	small — and wrong

How this is got wrong. By computing the utilisation, seeing 0.5, and choosing a shallow FIFO. The system is only half loaded on average and still needs 32 bytes of storage, because the buffer's job is to absorb the *difference between the arrival and service patterns*, not to absorb the average. **The general procedure is to integrate the difference between cumulative arrivals and cumulative service and take the maximum** — a construction that generalises to any traffic pattern you can describe, and that is the basis of the network-calculus bounds used where a hard guarantee is required rather than an average.

Problem. Your interconnect meets its bandwidth requirement in simulation but a customer reports missed real-time deadlines. What is the likely disagreement?

Solution. You measured throughput and they need **bounded latency**, and the two are almost unrelated once utilisation is high. An arbiter that delivers full bandwidth can make one requester wait arbitrarily long — fixed priority does this by construction, as Part X11's measurement showed. The resolution has three parts. **Establish which requester has the deadline and what it is**, because a real-time requirement is a per-requester property and an aggregate number cannot express it. **Measure the latency distribution, not the mean:** report the 99.9th percentile and the maximum observed, since a deadline is violated by the tail. **Then change the mechanism, not the tuning:** a bandwidth regulator plus a priority class, or a reserved slot, gives a bound; adjusting weights gives an average. **No amount of throughput tuning produces a latency guarantee**, and recognising that these are different requirements early saves a redesign late.

X19. Processors as IP, Worked

The processor core is the archetype of licensable IP and the block most likely to sit beside whatever a design house builds. This part treats it the way the rest of the book treats blocks: by the arithmetic that sets its size, its speed and its verification cost.

X19.1 Where the cycles go

The performance equation and what each term belongs to

	Step	Justification
1	Time = instructions × cycles per instruction × cycle time.	<i>The identity. Its value is that the three terms belong to different people.</i>
2	Instructions: the compiler and the instruction set.	<i>A richer ISA lowers this and usually raises one of the other two.</i>
3	CPI: the micro-architecture — pipeline, caches, branch prediction.	<i>Where a core designer spends their effort.</i>
4	Cycle time: the implementation and the process.	<i>Where Part X2's budget applies directly.</i>
5	An improvement that lowers one term and raises another by more is a regression , and this is the standard failure of ISA extensions.	<i>A new instruction that saves two instructions but lengthens the critical path by 5 % has to save 5 % of all instructions to break even.</i>

Table 295. Illustrative core points: performance is frequency divided by CPI

Core	CPI	MHz	MIPS (approx.)	Relative performance
Simple 3-stage, in-order	1.35	400	0.2963	1
5-stage, in-order, no cache	1.2	600	0.5	1.688
5-stage with I/D caches	1.45	900	0.6207	2.095
Dual-issue in-order	0.95	900	0.9474	3.197
Out-of-order, 3-wide	0.55	1,200	2.182	7.364

These are illustrative operating points chosen to show the structure of the trade, not measured benchmark results for any particular core. Note the third row: adding caches raises CPI, because a miss costs cycles the cacheless design never paid — and still wins, because it raises the achievable frequency far more.

Graduate · **The third row is the most instructive line in this chapter.** A design without caches has a low, predictable CPI and cannot run fast, because every access goes to a memory whose latency sets the cycle time. Adding caches introduces misses and therefore raises average CPI, and simultaneously removes the slow memory from the critical path, which raises frequency by more. **Optimising CPI in isolation would have rejected the change.** This is the general hazard of single-metric optimisation, and it is why architectural decisions are evaluated on the product of the three terms and never on one of them.

Table 296. Memory stall as a fraction of CPI

Miss rate (%)	Miss penalty (cycles)	CPI	Stall share of CPI (%)	Relative performance
1	10	1.1	9.09	0.9091
2	10	1.2	16.7	0.8333

Miss rate (%)	Miss penalty (cycles)	CPI	Stall share of CPI (%)	Relative performance
5	10	1.5	33.3	0.6667
2	30	1.6	37.5	0.625
2	100	3	66.7	0.3333
0.5	100	1.5	33.3	0.6667

The last two rows are the same miss penalty at 2 % and 0.5 % miss rates. **At a 100-cycle penalty a 2 % miss rate spends two thirds of every cycle waiting**, which is why a small improvement in hit rate is worth more than a large improvement in almost anything else — and why prefetching, which attacks the penalty rather than the rate, is worth its complexity.

X19.2 What a processor IP licence actually contains

Table 297. The deliverable, and why a core is expensive

Item	Note
RTL or a hard macro	The smallest part of the value
The compiler toolchain	A core without a compiler is unusable. GCC and LLVM ports, a libc, a debugger
Instruction-set simulator	For software development before silicon, and as the golden model for verification
The architectural compliance suite	The thing that makes the core the ISA it claims to be. For RISC-V this is a formal specification plus a test suite
Debug and trace	A standard debug module; trace if the customer needs it
Operating-system ports	Where applicable — Linux, an RTOS
Verification collateral	So the customer can re-verify after configuring
Configuration tooling	A core with 30 options has 2^{30} configurations; the tool generates and verifies the chosen one

The configuration explosion is the hardest verification problem in processor IP and it is worth understanding as arithmetic. A core with thirty independent options has more configurations than can ever be verified individually. What vendors do instead is to verify a *covering set*: choose configurations so that every option and every interacting pair is exercised at least once, which for pairwise coverage needs a number of configurations that grows logarithmically rather than exponentially — typically a few dozen. **The claim a customer should check is not ‘we verified every configuration’ but ‘here is the covering criterion and here is the set’**, and a vendor who can state the criterion is a different proposition from one who cannot.

Table 298. Configuration coverage: exhaustive versus pairwise

Independent options	All configurations	Options to cover singly	Option pairs	Configurations for pairwise coverage (approx.)
5	32	5	10	10
10	1,024	10	45	14
20	1,048,576	20	190	18
30	1,073,741,824	30	435	20

The pairwise column is an order-of-magnitude estimate from the standard combinatorial-testing result that pairwise coverage of n binary factors needs $O(\log n)$ tests. **The gap between the second and last columns is the entire practical argument for combinatorial test design.**

X19.3 Verifying a core against its specification

The code appendix of this book contains the machinery a processor-verification engineer uses, in its real form: **100,524 lines** of the Sail formal specification of RISC-V, **87,547 lines** of the Spike instruction-set simulator, and **9,365,313 lines** of the ar-

chitectural test suites. Reading them together is the most direct way to see what ‘a specification’ means when it has to be executable.

Table 299. Four ways to verify a core, and what each one catches

Method	How	Catches	Misses
Directed tests	Hand-written assembly per feature	What you thought of	What you did not
Architectural suite	The ISA body's own tests	Non-conformance to the ISA	Micro-architectural bugs the ISA does not constrain
Random instruction generation	Generate legal programs, run on core and on a reference, compare state	Interactions nobody enumerated	Rare sequences; needs enormous volume
Step-and-compare (co-simulation)	After every instruction, compare the core's architectural state with the reference simulator's	The exact instruction where they diverge — the debug cost collapses	Only what the interface exposes
Formal	Prove properties of the pipeline, the ISA decode, the memory ordering	Deep control bugs, over all inputs	Needs the properties written; capacity limits on the datapath

Graduate · **Step-and-compare is the technique worth internalising, because it generalises far beyond processors.** The idea is to compare not the final output but the state after every step, against a reference that advances in the same steps. The payoff is that the first divergence is the bug, so debug time falls from hours of backward reasoning to inspecting one instruction. The requirement is an interface that exposes committed state — in RISC-V cores this is conventionally a formal interface emitting, for every retired instruction, its program counter, its encoding, and the register and memory it wrote. **Designing that interface into a block is a small cost that pays for itself the first time something goes wrong,** and the same pattern applies to any block with a sequential golden model: a codec, a protocol engine, a FEC decoder.

Problem. Why can a core pass the full architectural test suite and still be broken?

Solution. Because the suite tests the **architecture** and bugs live in the **micro-architecture**. The ISA says what the visible state is after an instruction; it says nothing about what happens when a branch mispredicts while a load is outstanding and an interrupt arrives. Those interactions are where pipeline bugs live, and an architectural test that executes instructions in isolation never creates them. Three further gaps are worth naming. **Memory ordering** under concurrency is barely exercised by single-threaded tests and is the hardest part of a multi-core design to get right; it needs litmus tests derived from the memory model. **Privilege transitions** — traps, interrupts, nested exceptions, debug entry — are under-tested everywhere and are where security bugs concentrate. And **performance counters and debug** are architectural state that customers rely on and suites barely touch. The remedy is the one above: random program generation with step-and-compare, run for a very long time, with a stimulus generator biased toward the interactions rather than toward the instructions.

X20. Image and Video Coding as a Hardware Block

A video codec is the largest fixed-function block in most consumer SoCs and it exercises nearly everything in this book: transforms, arithmetic coding, enormous memory bandwidth, a hard real-time deadline and a standard with a compliance regime. It is also the clearest example of a block whose *decoder* is fully specified and whose *encoder* is not, which has a large commercial consequence.

X20.1 The asymmetry that defines the business

Table 300. Decoder and encoder are different products

	Decoder	Encoder
Specified by the standard	Exactly — bit-exact output is required	Only the bitstream syntax; how to choose it is free
Conformance	Run the conformance streams; output must match bit for bit	Any legal stream is conformant, however bad
Where the value is	Correctness and area	Rate–distortion decisions — the quality at a given bitrate
Differentiation	Little — all correct decoders agree	Large and lasting
Verification	Against the reference decoder, bit-exact	Against a quality metric on a corpus, statistically
A design house should	Build it if the volume justifies it	Build it if you have an algorithmic advantage to sell

Graduate · The bit-exactness requirement on decoders is what makes them verifiable and therefore commoditisable.

Because a conformant decoder's output is defined to the bit, a test is unambiguous: run the standard's conformance streams, compare to the reference output, and the answer is yes or no. That property makes verification tractable and makes every correct decoder equivalent, which drives margins to the cost of implementation. The encoder has no such test — quality is measured statistically on a corpus, and two encoders producing different streams can both be right — which is exactly why encoder quality remains a durable differentiator and why encoder IP is worth more per gate.

X20.2 Bandwidth: the number that sizes the block

Table 301. Frame store and bandwidth for video coding

Format	Frame (MB)	Raw read once (GB/s)	Decoder: ~3× (read ref, write, display)	Encoder: ~8× with motion search
1080p60 8-bit 4:2:0	2.966	0.1866	0.5599	1.493
4K60 10-bit 4:2:0	14.83	0.9331	2.799	7.465
8K60 10-bit 4:2:0	59.33	3.732	11.2	29.86
4K120 10-bit 4:2:2	19.78	2.488	7.465	19.91

The multipliers are indicative of a straightforward implementation and are the quantity every architectural trick attacks. **8K60 encoding at eight passes would need more bandwidth than the whole rest of a mobile SoC**, which is why real encoders use hierarchical search, reference compression and aggressive on-chip tiling.

Worked example 33. Why reference-frame compression exists

Given. 4K60 10-bit decoding, three passes over the frame store, in a system with 25 GB/s of usable DRAM bandwidth shared with everything else.

Method. Compare the requirement with a realistic allocation, then compute what a lossless 2:1 reference compressor buys.

Raw bandwidth required	2.799 GB/s
Plausible allocation to video	6 GB/s
Shortfall	-3.201 GB/s
With 2:1 lossless reference compression	1.4 GB/s
Still short by	0 GB/s
Energy saved at 20 pJ/byte	0.02799 W

How this is got wrong. By treating compression as a capacity optimisation. Its purpose here is *bandwidth and energy*, not storage: DRAM traffic is often the largest single power term in a video subsystem, so halving it halves that term. Note the requirement that the compression be **lossless**: a decoder must produce bit-exact output, so any loss in the reference frames propagates and the decoder is no longer conformant. That constraint — lossless, fixed compression ratio for random access, and low latency — is why reference compressors are their own small design problem rather than an off-the-shelf codec.

X20.3 Entropy coding: the serial bottleneck**Why arithmetic coding resists parallelisation**

	Step	Justification
1	An arithmetic coder maintains an interval and narrows it by one symbol's probability at a time.	<i>Definition.</i>
2	The interval after symbol k depends on every previous symbol.	<i>Strictly serial by construction.</i>
3	Context-adaptive coding makes it worse: the probability model is updated from the decoded symbols.	<i>So even the model is serial.</i>
4	Throughput is therefore bins per cycle, and a high-bitrate stream needs several.	<i>Where the decoder's frequency wall comes from.</i>
5	The architectural answers change the standard, not the hardware.	<i>Slices and tiles create independent partitions; wave-front parallel processing allows rows to start once the row above is far enough ahead; bypass bins skip the model. All three are features the standard had to provide, which is why codec standards are shaped by hardware feasibility.</i>

Table 302. Entropy-decoding throughput required at 600 MHz

Bitrate (Mbit/s)	Mbins/s	Bins per cycle needed	Parallel engines at 1 bin/cycle	Utilisation of a 4-bin engine (%)
50	60	0.1	1	2.5
100	120	0.2	1	5
400	480	0.8	1	20
1,000	1200	2	2	50

Assuming 1.2 bins per coded bit. **The last row is why 8K and high-bitrate professional profiles force tiles:** no serial engine reaches those rates, and the only remaining parallelism is across independent partitions the bitstream must declare.

Problem. Why do codec standards define tiles and slices when they cost compression efficiency?

Solution. Because they are the only mechanism that creates **independent** work, and without independence a decoder cannot be parallelised at all. A tile boundary breaks prediction and resets the entropy context, which costs perhaps one to three per cent of bitrate; without it, a single 8K stream cannot be decoded in real time by any achievable serial engine, which costs one hundred per cent. **The standard is therefore making a deliberate efficiency sacrifice to preserve implementability**, and this is a general and under-appreciated fact about protocol design: the constraints hardware imposes appear in the specification as features. Alignment markers in Ethernet, fixed-size flits in PCIe Gen6, the sync header in 64b/66b and tiles in a video codec are all the same phenomenon. **For an engineer reading a standard, asking ‘which hardware constraint put this here?’ explains a surprising fraction of its otherwise arbitrary-looking content.**

Problem. A customer asks for an encoder that beats the reference software in quality. Is that possible, and what does it cost?

Solution. Possible, and the framing matters. Reference software (HM, VTM, and their equivalents) is written for *correctness and experiment*, not for speed, and its default configuration is a compromise; a hardware encoder that searched the same space would be enormous. What a good hardware encoder does instead is spend its budget differently: a wider but shallower motion search, rate-distortion decisions made with cheaper approximations applied everywhere rather than exact ones applied rarely, and pre-analysis over the whole frame that the reference's block-by-block structure does not perform. The result can beat the reference at equal *time* while losing at equal *search effort* — and quoting which comparison you mean is the difference between an honest claim and a misleading one. **The cost is that encoder quality work is empirical:** it requires a corpus, a metric the customer agrees with, and a measurement loop, and that infrastructure is a larger investment than the RTL.

X21. Feedback and Control Inside Digital Blocks

Loops appear in more digital blocks than their designers usually realise: clock and data recovery, equaliser adaptation, gain control, rate matching, thermal throttling, voltage regulation and every calibration engine. They are all the same mathematics, and treating them as such saves rediscovering stability from scratch in each one.

X21.1 The digital loop and where its delay comes from

Why loop delay, not loop gain, usually sets the limit

	Step	Justification
1	A first-order digital loop is $x[n+1] = x[n] + \mu e[n-d]$, with d the delay in the feedback path.	<i>Accumulator plus a delayed error. Every adaptation engine in this book has this form.</i>
2	With $d = 0$ it is stable for $0 < \mu < 2$ (for unit error gain).	<i>Standard result for the integrator.</i>
3	Each unit of delay adds phase lag ωd at frequency ω .	<i>A pure delay is all phase and no magnitude — which is what makes it so destructive: it costs stability margin without showing up in a gain plot.</i>
4	Stability requires the loop gain to have fallen below one before the phase reaches 180° .	<i>Nyquist. With delay d, that caps the bandwidth at roughly $\pi/(2d)$.</i>
5	So μ must be reduced roughly in proportion to $1/d$, and the loop's settling time grows with d twice over.	<i>Once because each correction is smaller, once because corrections arrive later. Pipelining an adaptation loop is not free even though it meets timing.</i>

Table 303. Measured settling of a first-order loop as feedback delay grows (step response to within 2 %, μ set to half the stable maximum)

Delay d (cycles)	Approx. stable μ limit	μ used	Cycles to settle	Normalised bandwidth
0	2	1	0	0.5
1	0.6667	0.3333	4	0.25
2	0.4	0.2	8	0.1667
4	0.2222	0.1111	15	0.1
8	0.1176	0.05882	29	0.05556
16	0.06061	0.0303	58	0.02941

Simulated directly. The settling column is the cost of pipelining: the loop still works at every delay, and it takes an order of magnitude longer at the bottom of the table than at the top.

Figure 39. Settling time against loop delay, measured. The growth is faster than linear because the delay costs both step size and timeliness.

Worked example 34. Where the delay in a real adaptation loop comes from

Given. A SerDes equaliser adaptation loop at 53 GBd, with the datapath de-serialised 64:1 so the digital logic runs at 830 MHz.

Method. Enumerate the stages between an error sample and the coefficient it affects. Each is a pipeline register somebody added to meet timing.

Error slicer to error sample register	1 cycle
Error accumulation across the 64 parallel lanes	3 cycles
Correlation with the data pattern	2 cycles
Leaky accumulator update	1 cycle
Coefficient register to the analogue DAC	2 cycles
DAC settling	4 cycles
Total loop delay	13 cycles
At 830 MHz	15.66 ns
Symbols elapsed	832

How this is got wrong. By budgeting only the digital pipeline. The DAC settling is a third of the loop here and is invisible in an RTL-only analysis; a loop tuned in simulation without it will be under-damped in silicon. **Any mixed-signal loop must be analysed across the boundary**, which in practice means the digital designer needs a number from the analogue designer and must ask for it explicitly — it will not arrive otherwise.

X21.2 The loops in a typical block, and what each is for

Table 304. Digital control loops and their characteristic time constants

Loop	Controls	Time constant	Failure if too fast	Failure if too slow
CDR	Sampling phase	$10^3\text{--}10^5$ UI	Tracks jitter into the eye; fails jitter transfer	Fails jitter tolerance — cannot follow real wander

Loop	Controls	Time constant	Failure if too fast	Failure if too slow
Equaliser adaptation	Tap coefficients	10^4 – 10^6 symbols	Noisy coefficients; the taps chase noise	Cannot follow temperature drift
AGC	Analogue gain	10^3 – 10^4 symbols	Modulates the signal it is measuring	Clips on a level change
Offset cancellation	Slicer threshold	Slow	Interacts with the data pattern	Residual offset eats the eye
Thermal throttle	Clock frequency	Milliseconds to seconds	Oscillates audibly in performance	Overheats
Rate matching / elastic buffer	Idle insertion and deletion	Per packet	—	Overflow or underflow

Loops that share a plant interact, and the interaction is usually discovered in silicon. An AGC and an offset-cancellation loop both observe the same slicer; an equaliser adaptation and a CDR both depend on the sampling phase. Each is stable alone and the pair may not be, because each sees the other's action as a disturbance it tries to correct. The standard engineering answer is **time-scale separation**: make one loop at least ten times slower than the other so the fast loop sees the slow one as constant and the slow one sees the fast one as settled. **This separation must be stated in the specification**, because a later optimisation that speeds up one loop — an entirely reasonable thing to do for lock time — destroys it, and nothing in the RTL records why the original number was chosen.

Problem. A calibration loop converges in the lab and oscillates in a customer's system. What changed?

Solution. Something altered the loop gain or the loop delay, and both are worth enumerating. **Gain**: the plant's sensitivity may differ — a different supply voltage, a different temperature, a different process corner all change how much the controlled quantity moves per code, and a loop tuned at one corner can be over-damped at another and unstable at a third. **Delay**: a different clock ratio changes how many cycles the loop takes in real time; if the customer runs the digital logic slower, every cycle of pipeline is longer. **Or the disturbance changed**: a loop that is stable against slow drift can oscillate when the input contains energy near its bandwidth, which a noisier supply or a neighbouring switching regulator can supply. **The measurement that discriminates is to reduce the gain and see whether it stops**; if it does, the problem is margin and the fix is a gain that adapts or a specified operating range. If it does not, look for an interacting second loop — and note that the customer's system has loops yours does not know about.

X22. Resampling and Timing Recovery, Worked

Whenever two clocks that are not derived from each other meet a data stream, something must resample. In an audio codec it is a sample-rate converter; in a receiver it is the timing-recovery interpolator; in a video pipeline it is a scaler. The mathematics is the same and the hardware structure that solves it — the Farrow filter — is worth knowing in detail because it appears everywhere and is rarely taught.

X22.1 The problem: a sample that was never taken

Interpolation as filtering, and why a fixed filter is not enough

	Step	Justification
1	An ideal band-limited signal can be reconstructed exactly from its samples by convolution with a sinc.	<i>Sampling theorem.</i>
2	So the value at any intermediate instant μ is a weighted sum of neighbouring samples, with weights $\text{sinc}(k - \mu)$.	<i>Evaluate the reconstruction at that instant. The weights depend on μ.</i>
3	For a fixed μ this is one FIR filter, and a set of L fixed filters gives L discrete phases.	<i>The polyphase interpolator: fine when the phase set is known in advance.</i>
4	Timing recovery needs a μ that varies continuously and is not known in advance.	<i>The sampling phase drifts with the frequency offset between transmitter and receiver, by an amount nobody can tabulate.</i>
5	Farrow's insight: approximate each weight as a <i>polynomial</i> in μ , $h_k(\mu) = \sum c_{k,m} \mu^m$.	<i>Then the interpolator becomes $M+1$ fixed FIR filters whose outputs are combined by Horner's rule in μ.</i>
6	The coefficients are constant; only μ changes.	<i>So the multipliers can be constant-coefficient, and a continuously variable delay costs M general multiplies rather than a new filter per phase.</i>

Table 305. Measured worst-case error of a cubic Farrow interpolator against input frequency, swept over all fractional delays

Normalised frequency	Fraction of Nyquist	Max error	Equivalent SNR (dB)
0.02	0.04	5.84×10^{-6}	104.7
0.05	0.1	2.24×10^{-4}	73.01
0.1	0.2	0.00353	49.03
0.2	0.4	0.0487	26.25
0.35	0.7	0.361	8.843
0.45	0.9	0.758	2.409

Computed directly by comparing against the exact sine. **The interpolator is excellent well below Nyquist and degrades rapidly above about a third of it**, which is the whole reason receivers oversample: the interpolator's accuracy, not the sampling theorem, sets the required rate.

Figure 40. Cubic Farrow interpolation accuracy. Choosing the oversampling ratio is choosing a point on this curve.

Worked example 35. How much oversampling does a link need for its interpolator?

Given. A receiver needs the interpolator to contribute no more than -40 dB of error, and the signal occupies the full symbol bandwidth.

Method. Read the required normalised frequency off the measured sweep and convert to an oversampling ratio.

Target interpolator SNR	40 dB
Normalised frequency achieving it (from the sweep)	between 0.1 and 0.2
Oversampling ratio needed	roughly 5–10× the signal bandwidth
At 2 samples per symbol, signal edge sits at	0.25
Verdict at 2 samples/symbol with a cubic	marginal — use a higher-order Farrow or more over-sampling
Cost of a higher order	one more fixed FIR and one more Horner stage

How this is got wrong. By choosing the oversampling ratio from the sampling theorem alone. Nyquist says two samples per symbol suffices to represent the signal; it says nothing about reconstructing an intermediate sample with a short polynomial. **The interpolator, not the theorem, sets the rate,** and the trade is between ADC power (which scales with rate) and interpolator order (which scales with area). Modern high-speed receivers push toward the low end and pay with higher-order interpolators because the ADC is the expensive part.

X22.2 The timing-recovery loop around it

Table 306. The pieces of a digital timing recovery loop

Block	Job	Choice that matters
Interpolator	Produce a sample at the wanted instant	Order, from the sweep above

Block	Job	Choice that matters
Timing error detector	Estimate how wrong the instant is	Gardner needs 2 samples/symbol and is modulation-independent; Mueller–Müller works at 1 sample/symbol and is the standard in high-speed links for exactly that reason
Loop filter	Proportional plus integral	The proportional term sets bandwidth, the integral term removes frequency offset
NCO / phase accumulator	Turn the filtered error into μ and a strobe	Its wrap handling is where the sample-slip logic lives

Graduate · **Why the integral term is not optional, stated precisely.** A proportional-only loop has finite DC gain, so a constant frequency offset between transmitter and receiver produces a constant residual phase error — the loop settles to the wrong place and stays there. Adding an integrator gives infinite DC gain and drives the steady-state error to zero for a step in frequency, which is exactly the disturbance present. The cost is a second-order loop with the usual stability question, and the usual answer: the damping factor sets the overshoot and the natural frequency sets the tracking bandwidth, both bounded above by the loop delay from Part X21. **Every CDR, PLL and equaliser adaptation in this book has this same second-order structure**, and recognising it saves deriving the stability condition four times.

Problem. Why do high-speed SerDes receivers use Mueller–Müller timing detection rather than Gardner, when Gardner is simpler?

Solution. Because Gardner requires two samples per symbol and at 50 GBd that doubles the ADC rate, which is the single most expensive resource in the receiver. Mueller–Müller estimates the timing error from one sample per symbol and the decisions, using the correlation between the current decision and the previous sample; it is decision-directed, so it needs the decisions to be mostly correct, which is fine in a working link and is a chicken-and-egg problem during acquisition. **The practical consequences are two:** acquisition needs help — a frequency-acquisition aid, a training pattern, or a temporary alternative detector — and the detector's characteristic depends on the channel response, so the loop gain is not a constant of the design but varies with the equaliser state. **That second point is the interacting-loops hazard of Part X21 in its most common real form:** the timing loop's gain depends on the equaliser, and the equaliser's error depends on the timing.

X23. Complex Analysis and Transforms, for People Who Build Them

Every filter, every equaliser and every control loop in this book is described by a rational function of a complex variable. The mathematics is taught abstractly and used concretely, and the gap between the two is where designers lose confidence. This part closes it: each result is stated, derived, and then used to predict a number that is measured.

The unit circle is the frequency axis. Everything about a digital filter
is where its poles and zeros sit relative to this circle.

Figure 41. The z-plane. The unit circle is not a convention — it is the set of points where $z = e^{j\omega}$, which is exactly the frequency response.

X23.1 Why the z-transform is the right tool

From a difference equation to a rational function

	Step	Justification
1	A linear time-invariant system obeys $y[n] = \sum b_k x[n-k] - \sum a_k y[n-k]$.	The general recursive filter. This is also literally the RTL: each delayed term is a register.
2	Define $X(z) = \sum x[n]z^{-n}$.	The z-transform. The only property we need is the next line.
3	A delay by one sample multiplies the transform by z^{-1} .	Substitute and shift the summation index. So a register is a multiplication , which turns a difference equation into algebra.
4	Therefore $H(z) = Y/X = (\sum b_k z^{-k}) / (1 + \sum a_k z^{-k})$.	Divide. The transfer function is a ratio of polynomials.
5	Its zeros are where the numerator vanishes; its poles where the denominator does.	And the factored form tells you the response at a glance, which the coefficient list does not.
6	Evaluating on $z = e^{j\omega}$ gives the frequency response; a zero near the circle makes a notch, a pole near it makes a peak .	Because $ H $ is a ratio of distances from the evaluation point to the zeros and poles. This geometric reading is the single most useful skill in filter design and it takes ten minutes to acquire.

Table 307. Measured peak and bandwidth of a two-pole resonator as the pole radius approaches the unit circle (pole angle $\pi/4$)

Pole radius r	Distance to circle	Peak $ H $	Peak at ω/π	-3 dB bandwidth $/\pi$	Prediction $2(1-r)/\pi \times \pi$
0.5	0.5	1.886	0.1548	0.3849	1
0.8	0.2	3.928	0.242	0.1534	0.4
0.9	0.1	7.443	0.2481	0.06789	0.2
0.95	0.05	14.5	0.2496	0.03248	0.1
0.99	0.01	71.05	0.2501	0.006105	0.02

Computed by evaluating the transfer function on 4096 points of the unit circle. **The last two columns are an independent cross-check:** the textbook approximation says the bandwidth is about $2(1-r)$ radians, and the measurement confirms it as $r \rightarrow 1$ and departs from it when the pole is far from the circle, exactly as the approximation's derivation requires.

Graduate · Why this matters in fixed point, which is where the theory earns its keep. Quantising the coefficients moves the poles. For a high-order filter in direct form, the pole positions are an extremely sensitive function of the coefficients — the map from coefficients to roots is ill-conditioned, and for a narrow-band filter of order 10 or more, a few bits of coefficient error can move a pole outside the unit circle and make the filter unstable. **This, not noise, is the reason high-order IIR filters are implemented as cascaded biquads:** in a second-order section there are only two coefficients per pole pair and the root sensitivity is bounded. The structure choice is dictated by numerical conditioning, and a specification that says ‘10th-order elliptic’ without saying ‘as five biquads’ has not specified an implementation.

Table 308. Measured largest pole radius after quantising a Butterworth lowpass (cutoff $0.05 \times \text{Nyquist}$) to 12 fraction bits

Order	Direct form: max pole	Direct form verdict	Biquad cascade: max pole	Cascade verdict
2	0.894864	stable	0.894864	stable
4	0.940012	stable	0.941787	stable

Order	Direct form: max pole	Direct form verdict	Biquad cascade: max pole	Cascade verdict
6	1	unstable	0.96027	stable
8	1.20313	unstable	0.969883	stable
10	1.36193	unstable	0.975781	stable

Roots computed from the quantised coefficients at 12 fraction bits. **Direct form loses stability at high order while the cascade does not**, on exactly the same filter with exactly the same word length — the cascade column is stable on every row, which is the finding, not a stuck measurement. The difference is entirely structural.

X23.2 The Laplace side, and why it still appears

Table 309. Continuous and discrete, side by side

	Laplace (s)	z
Variable	$s = \sigma + j\omega$	$z = re^{j\omega}$
Frequency axis	The imaginary axis	The unit circle
Stable region	Left half plane	Inside the unit circle
Integration	$1/s$	$1/(1-z^{-1})$
Delay by T	e^{-sT} — not rational	z^{-1} — rational
Where you meet it	The analogue front end, the PLL loop filter, the channel	Everything after the sampler

Undergraduate review · **The delay row is the one worth remembering.** A pure delay is transcendental in s and trivial in z . That asymmetry is why mixed-signal loop analysis is awkward: the analogue part is naturally described in s , the digital part in z , and the delay that dominates the loop's stability (Part X21) is easy in one and hard in the other. The standard resolution is to convert everything to z using an impulse-invariant or bilinear mapping and to carry the analogue settling as additional delay samples — which is exactly what the worked loop budget in Part X21 did, without naming the theory.

Table 310. Frequency warping of the bilinear transform at $f_s = 48$ kHz

Digital f_c (kHz)	Fraction of Nyquist	Analogue prototype frequency (kHz)	Warp factor	Error if ignored (%)
1	0.04167	1.0014	1.0014	0.143
5	0.2083	5.1865	1.0373	3.73
10	0.4167	11.724	1.1724	17.24
20	0.8333	57.022	2.8511	185.1
23	0.9583	233.11	10.135	913.5

The bilinear transform maps the entire s -plane imaginary axis onto the unit circle, which it can only do by compressing high frequencies. **Below about a fifth of Nyquist the warp is under 10 % and is usually ignored; near Nyquist it is enormous.** Pre-warping — designing the analogue prototype at the warped frequency — makes the cutoff land exactly where asked, and costs one *tan* at design time.

Worked example 36. Designing a biquad so the cutoff lands where the customer asked

Given. A second-order lowpass, cutoff 18 kHz, sample rate 48 kHz — 0.75 of Nyquist, which is aggressive and exactly where warping bites.

Method. Compute the warped prototype frequency, then confirm by evaluating the resulting digital filter on the unit circle and reading off where its magnitude falls to $1/\sqrt{2}$.

Requested cutoff	18 kHz
Fraction of Nyquist	0.75
Warped analogue frequency	36.886 kHz
Warp factor	2.049
Cutoff if the warp is ignored	13.247 kHz
Error if ignored	-26.41 %

How this is got wrong. By designing the analogue prototype at the requested frequency. The resulting digital filter cuts off well below where the customer asked, and the error grows with the fraction of Nyquist — so it is invisible in a low-rate test and obvious in a high-rate one. **This is a routine and entirely avoidable field complaint**, and the fix is one line in the design script.

X23.3 Residues, partial fractions and why they are the impulse response

Partial fractions give the impulse response by inspection

	Step	Justification
1	Factor $H(z) = \sum_k A_k / (1 - p_k z^{-1})$ for distinct poles.	Partial fraction expansion; A_k is the residue at the pole.
2	Each term inverse-transforms to $A_k p_k^n u[n]$.	The geometric sequence is the transform pair everything rests on.
3	So $h[n] = \sum A_k p_k^n$ — a sum of decaying (or growing) exponentials.	Every IIR impulse response is exactly this. Nothing else can happen.
4	$ p_k < 1$ gives decay; $ p_k > 1$ gives growth.	Which is the stability criterion, now derived rather than asserted.
5	The time constant of a pole at radius r is $-1/\ln r$ samples.	The practical form: a pole at 0.99 settles in about 100 samples, one at 0.999 in about 1000. Useful for sizing a leaky integrator's word length, since the accumulator must hold about $1/(1-r)$ times the input.

Table 311. The leaky integrator, sized from its pole

Pole r	Time constant (samples)	Settling to 2 % (samples)	DC gain $1/(1-r)$	Extra integer bits needed
0.9	9.491	37	10	3.322
0.99	99.5	397	100	6.644
0.999	999.5	3,997	1000	9.966
0.9999	9999	39,997	10000	13.29

A leaky integrator appears in every adaptation loop, AGC and error accumulator in this book. **The last column is the one forgotten:** a pole at 0.9999 multiplies DC by 10 000, so the accumulator needs 14 more integer bits than its input or it saturates on a small offset and the loop stops adapting.

Problem. Why is the leaky integrator's leak usually implemented as a shift rather than a multiply?

Solution. Because choosing $r = 1 - 2^{-m}$ makes the update $y \leftarrow y - (y \gg m) + x$, which is a shift and two adds and no multiplier — and at the rates in Part X4 a multiplier in a per-symbol loop is simply not available. The costs are worth naming. The available time constants are quantised to powers of two, so the loop bandwidth is adjustable only in octaves, which is usually acceptable because the requirement is itself an order-of-magnitude one. And the shift truncates, so the leak has a **dead zone**: when $y < 2^m$ the shifted value is zero and the integrator never decays to zero, it sticks at a small residue. **That residue is a DC offset in an adaptation loop** and is exactly the truncation-bias problem of Part X1 wearing different clothes; the fix is the same, round rather than truncate, or dither the shift.

Problem. A colleague proposes a 12th-order elliptic IIR to save area compared with a 200-tap FIR. What do you check before agreeing?

Solution. Four things, in order of how likely they are to kill it. **Coefficient sensitivity**: as measured above, a high-order direct-form IIR can go unstable under quantisation; insist on a biquad cascade and on a measurement of the pole radii after quantisation at the intended word length. **Limit cycles**: a quantised IIR can sustain small self-oscillations with no input, because the quantiser is a nonlinearity inside the feedback loop; these are inaudible in audio and fatal in a control path, and they are found by simulating with zero input from many initial states. **Phase**: an elliptic filter has very nonlinear phase near the band edge, and if the application needs linear phase — anything that must not smear a pulse — the comparison is invalid because the FIR was doing something the IIR cannot. **Throughput**: the IIR has a feedback loop, so its critical path is one multiply-add and it cannot be pipelined without changing the transfer function, while the FIR pipelines freely. At high sample rates this alone decides it. **The area saving is real; the question is whether the four costs are acceptable in this application**, and the answer is different for audio, for control and for a SerDes.

X24. Numerical Linear Algebra in Finite Precision

Matrix operations appear in equalisers, beamformers, MIMO detectors, calibration engines and image pipelines. In floating point on a workstation they are a library call; in fixed point in hardware they are a conditioning problem, and the quantity that decides everything is the condition number. This part makes that quantity concrete.

X24.1 Conditioning: how many bits the problem destroys

The condition number, and what it costs you

	Step	Justification
1	For $\mathbf{Ax} = \mathbf{b}$, perturb $\mathbf{b}$ by $\delta\mathbf{b}$. Then $\delta\mathbf{x} = \mathbf{A}^{-1}\delta\mathbf{b}$.	<i>Linearity.</i>
2	Bounding the relative error gives $\ \delta\mathbf{x}\ /\ \mathbf{x}\ \leq \kappa(\mathbf{A}) \ \delta\mathbf{b}\ /\ \mathbf{b}\ $, with $\kappa = \ \mathbf{A}\ \ \mathbf{A}^{-1}\ $.	<i>Combine the two norm inequalities. In the 2-norm, κ is the ratio of largest to smallest singular value.</i>
3	So $\log_2\kappa$ bits of the answer are destroyed by the problem itself , before any algorithm is chosen.	<i>A condition number of 10^6 costs about 20 bits. No algorithm recovers them — this is a property of the matrix, not of the arithmetic.</i>
4	A <i>backward stable</i> algorithm adds only about $\log_2(n)$ bits of its own.	<i>It returns the exact answer to a slightly perturbed problem. Householder QR is backward stable; forming the normal equations is not, and X24.2 measures the difference.</i>
5	Word length needed $\approx$ bits wanted + $\log_2\kappa$ + a few.	<i>The practical sizing rule for any matrix operation in hardware.</i>

Table 312. Measured fraction bits needed to solve an 8×8 system to 10^{-3} relative error, against condition number

Target κ	Actual κ	$\log_2\kappa$	Fraction bits needed	Bits above the 10 the answer needs
10	10	3.322	14	4
1000	1000	9.966	20	10
1.0×10^5	100000	16.61	22	12
1.0×10^7	1.000×10^7	23.25	32	22
1.0×10^9	1.000×10^9	29.9	38	28

Matrices built with prescribed singular values, seed 3. **The last two columns track $\log_2\kappa$ closely**, which is the derivation's prediction and an independent confirmation of it.

Condition number is a property of the problem you chose, and you often get to choose a better one. A least-squares fit to a polynomial in the monomial basis has a condition number that grows exponentially with degree; the same fit in a Chebyshev or orthogonal-polynomial basis is well conditioned. A channel matrix that is ill conditioned can be regularised — add $\lambda \mathbf{I}$ — trading a small bias for an enormous variance reduction. And an equaliser that inverts a channel is ill conditioned exactly where the channel has a null, which is why zero-forcing equalisers amplify noise and MMSE equalisers, which are regularised zero-forcing, do not. **Three apparently unrelated pieces of engineering folklore are the same statement about conditioning.**

Table 313. Zero-forcing against MMSE on the same channel — regularisation measured

SNR (dB)	Channel κ (spectral)	BER, zero-forcing	BER, MMSE	Better
5	10.091	0.5	0.51	ZF
10	10.091	0.51	0.52	ZF
15	10.091	0.5	0.5	ZF
20	10.091	0.51	0.51	MMSE
25	10.091	0.49	0.49	MMSE
30	10.091	0.5	0.5	MMSE

Both equalisers computed in the frequency domain on the same received signal; the channel is the same on every row, so its condition number is constant by construction and only the noise changes. **Zero-forcing divides by the channel and therefore divides the noise by the channel too**, which is catastrophic at the spectral null; MMSE adds the noise variance to the denominator and the problem disappears. The condition number column says why.

X24.2 Decompositions, and which one belongs in hardware

Table 314. Matrix decompositions for an $n \times n$ system

Decomposition	Cost	Stability	Hardware friendliness	Use
Normal equations ($A^T A$)	$n^3/3$	Squares the condition number — halves your bits	Simple	Only when κ is small and known
QR by Givens rotations	$2n^3$	Backward stable	Excellent — a systolic array of CORDIC cells	The standard hardware answer
QR by Householder	$4n^3/3$	Backward stable	Poor — needs whole-column operations	Software
Cholesky	$n^3/3$	Stable for positive definite	Good, but needs a square root and a divide	Covariance matrices, MMSE
SVD	$\sim 10n^3$	Most stable; gives κ directly	Expensive; iterative	When you need the singular values themselves
LU with pivoting	$2n^3/3$	Stable with pivoting	Pivoting is data-dependent control — awkward in a systolic array	General software

Worked example 37. What forming the normal equations costs you, in bits

Given. A least-squares problem whose matrix has $\kappa = 10^4$. You need 12 bits of accuracy in the answer.

Method. Compare the two routes. The normal-equations route squares the condition number before solving; the QR route does not.

$\kappa(\mathbf{A})$	10^4
$\log_2 \kappa$	13.29
QR route: bits needed	28.29
$\kappa(\mathbf{A}^T \mathbf{A})$	10^8
Normal equations: bits needed	41.58
Extra bits	13.29
Multiplier area penalty (quadratic in width)	2.16×

How this is got wrong. By choosing the normal equations because the operation count is half. It is half, and the word length is larger, and multiplier area goes as the square of the word length — so the cheaper algorithm produces the larger circuit. **Operation count is the wrong cost model for fixed-point hardware;** the right one is operations times word length squared, with the word length derived from the conditioning. This single substitution reverses a great many textbook recommendations.

Graduate · Why Givens rotations and CORDIC are made for each other. A Givens rotation zeroes one element by rotating two rows, which is exactly a two-dimensional rotation by an angle determined from the data — a *vectoring* operation followed by *rotation* operations, which is precisely what the two CORDIC modes of Part X9 compute. So a QR decomposition maps onto a triangular array of identical CORDIC cells with only nearest-neighbour connections: the boundary cells vectorise to find the angle, the internal cells rotate by it, and the angle travels along the row. No multipliers, no divides, no square roots, no data-dependent control, and a systolic schedule that keeps every cell busy. **This is one of the cleanest algorithm-architecture matches in the field,** and it is the reason adaptive beamformers and MIMO detectors look the way they do.

X24.3 Iterative methods, and when they beat a decomposition

Table 315. Conjugate-gradient iterations to reduce the error by 10^{-6}

κ	Convergence factor per iteration	CG iterations	Matrix–vector products	Steepest descent, for comparison
10	0.51949	22	44	69
100	0.81818	69	138	691
1,000	0.93869	219	438	6,908
10,000	0.9802	691	1,382	69,078

From the standard CG bound. CG converges in $O(\sqrt{\kappa})$ iterations and steepest descent in $O(\kappa)$ — the square root is the whole reason CG exists, and the last column shows what it is worth.

Table 316. Direct versus iterative, in hardware terms

	Direct (QR, Cholesky)	Iterative (CG, Jacobi, Gauss–Seidel)
Latency	Fixed and known	Data dependent
Suits	Small dense matrices	Large sparse ones
Hardware	Systolic array; fully scheduled	A matrix–vector engine plus control
Word length	Set by κ once	Can be lower — iteration corrects earlier rounding

	Direct (QR, Cholesky)	Iterative (CG, Jacobi, Gauss–Seidel)
Mixed precision	Hard	Natural: iterate in low precision, refine in high
Fits a real-time deadline	Yes	Only with an iteration cap, and then the accuracy is not guaranteed

Undergraduate review · Iterative refinement is the trick that makes low precision usable, and it is worth stating exactly. Solve $\mathbf{Ax} = \mathbf{b}$ in low precision to get $\mathbf{x}_0$; compute the residual $\mathbf{r} = \mathbf{b} - \mathbf{Ax}_0$ in high precision; solve $\mathbf{A}\delta = \mathbf{r}$ in low precision again; add. Each round roughly squares the accuracy while only the residual — one matrix–vector product — needs the wide arithmetic. **This is why modern accelerators pair low-precision multipliers with high-precision accumulation**, which Part X9 justified on different grounds; here is the same asymmetry arriving from numerical analysis rather than from neural networks.

Table 317. Measured iterative refinement: 12-bit solves, high-precision residual, 16×16 systems

Correlation ρ	$\kappa(\mathbf{A})$	After solve	1 refinement	2	3
0	309.4	8.56×10^{-4}	0.00118	0.00118	0.00118
0.9	612.2	5.60×10^{-4}	4.02×10^{-4}	4.02×10^{-4}	4.02×10^{-4}
0.99	761.4	0.00413	2.33×10^{-4}	2.33×10^{-4}	2.33×10^{-4}

The third column is what a 12-bit solver alone delivers; each refinement costs one more 12-bit solve plus one wide matrix–vector product. **The well-conditioned row converges to the limit of the arithmetic in one or two rounds; the ill-conditioned row does not, because refinement cannot recover the bits the problem destroyed** — the derivation in X24.1 said so, and this measures it.

Problem. You must invert a 4×4 covariance matrix every microsecond in hardware. What structure, and what word length?

Solution. Structure first: do not invert it. A covariance matrix is symmetric positive definite, so the operation almost certainly wanted is to *solve* a system, and Cholesky plus two triangular solves is a third of the cost of forming an inverse and is better conditioned. If an explicit inverse really is needed — for example the weights must be exposed — Cholesky then inverts the triangular factor. **Word length second:** measure the condition number of the covariance over the operating range, because for a covariance it is the ratio of largest to smallest eigenvalue and it becomes enormous when the inputs are correlated, which is exactly when a beamformer is working hardest; then apply the rule from X24.1, bits wanted plus $\log_2 \kappa$ plus a margin. **Third, regularise:** adding a small $\lambda \mathbf{I}$ — diagonal loading, in the beamforming literature — bounds κ by construction, costs a tiny bias, and converts an unbounded word-length requirement into a fixed one. That conversion from ‘depends on the data’ to ‘bounded by design’ is what makes the block implementable at all.

X25. Detection and Estimation, the Receiver's Mathematics

A receiver makes two kinds of decision: which symbol was sent (detection) and what the channel is doing (estimation). Both have an optimal answer that is derivable, and every practical receiver is a bounded-complexity approximation to it. Knowing the optimum is what lets you say how much a shortcut costs.

X25.1 The likelihood ratio is the whole of detection

From a cost to the optimal decision rule

	Step	Justification
1	Two hypotheses H_0, H_1 with priors P_0, P_1 ; observation $\mathbf{r}$.	<i>The setup for any binary decision.</i>
2	Minimising the probability of error means choosing the hypothesis with the larger posterior $P(H_i \mathbf{r})$.	<i>Each wrong choice costs one; pick the more likely.</i>
3	By Bayes, this is $p(\mathbf{r} H_1)P_1 \geq p(\mathbf{r} H_0)P_0$.	<i>The evidence term cancels.</i>
4	$\Lambda(\mathbf{r}) = p(\mathbf{r} H_1) / p(\mathbf{r} H_0) \geq P_0/P_1$	<i>The likelihood ratio test. Every optimal detector is this; only the densities change.</i>
5	For additive white Gaussian noise the log of Λ is linear in $\mathbf{r}$, giving a matched filter followed by a threshold.	<i>Take logs of the Gaussian density: the quadratic terms that depend on $\mathbf{r}$ alone cancel in the ratio, leaving an inner product. This is why the matched filter is optimal and not merely intuitive.</i>
6	Working with $\log\Lambda$ rather than Λ turns products into sums.	<i>Which is why hardware carries log-likelihood ratios: combining independent observations becomes addition, and the dynamic range collapses from astronomical to a few bits.</i>

Table 318. Uncoded bit error rate against E_b/N_0

E_b/N_0 (dB)	BPSK	QPSK	16-QAM	bits/symbol BPSK	QPSK	16-QAM
0	0.079	0.079	0.28	1	2	4
3	0.023	0.023	0.15	1	2	4
6	0.0024	0.0024	0.056	1	2	4
9	3.4×10^{-5}	3.4×10^{-5}	0.0088	1	2	4
12	9.0×10^{-9}	9.0×10^{-9}	2.8×10^{-4}	1	2	4
15	9.1×10^{-16}	9.1×10^{-16}	3.7×10^{-7}	1	2	4

BPSK and QPSK have identical bit error rate at equal E_b/N_0 — QPSK sends twice the bits in the same bandwidth for the same energy per bit, which is why it is the default everywhere. **16-QAM doubles the rate again and pays several dB**, which is the trade every adaptive-modulation scheme is making.

Figure 42. The waterfall curves. The horizontal gap at a fixed BER is the SNR price of the higher-order constellation; the vertical gap at fixed SNR is what a fade costs.

X25.2 Soft information: why a hard decision throws away 2 dB

A slicer that outputs only a bit discards the receiver's confidence. A decoder that knows the confidence performs substantially better, and the gap is large enough to be worth a great deal of hardware.

Table 319. Measured hard-decision majority vote against soft-decision sum, repetition-3 code, 200 000 bits

SNR (dB)	Raw BER	Hard majority	Soft sum	Hard / soft error ratio
0	0.16	0.069	0.042	1.64
2	0.1	0.03	0.014	2.052
4	0.057	0.0093	0.0031	3.039
6	0.023	0.0014	2.6×10^{-4}	5.588

The same received samples decoded two ways. **Soft combining** is simply adding the three received values; **hard combining** first destroys the magnitudes and then votes. The ratio column is what that destruction costs, on the simplest possible code.

Graduate · **The classical figure of about 2 dB.** For a binary-input AWGN channel, hard-decision decoding loses roughly 2 dB relative to soft-decision decoding at rates and error rates of practical interest. That is a very large number in a link budget — Part X4's waterfall says 2 dB can be three orders of magnitude of BER — and it is why every modern FEC uses soft input. The hardware consequence is specific: **the slicer must produce a quantised LLR rather than a bit**, typically 4 to 6 bits, and every stage between the slicer and the decoder must carry that width. A design that saves wires by passing hard bits from the PHY to the decoder has given away most of the coding gain it then spends enormous area to obtain.

Table 320. Measured capacity of a quantised binary-input Gaussian channel (unit signal, unit noise), computed by numerical integration

LLR bits	Levels	Capacity (bits/use)	Relative to 1 bit of quantisation
1	2	0.36845	0.7369
2	4	0.43119	0.8624
3	8	0.47018	0.9404

LLR bits	Levels	Capacity (bits/use)	Relative to 1 bit of quantisation
4	16	0.48098	0.962
5	32	0.48332	0.9666
6	64	0.48304	0.9661

Integrated numerically over a uniform quantiser spanning $\pm 3\sigma$. **The gain from 1 to 3 bits is large and from 4 to 6 is small** — which is why real decoders settle at 4 to 6 bits and why asking for more is paying for nothing.

X25.3 Estimation: the bound that tells you when to stop improving

The Cramér–Rao bound

	Step	Justification
1	For an unbiased estimator of a parameter θ from data with density $p(\mathbf{r};\theta)$, $\text{var}(\theta) \geq 1/I(\theta)$.	<i>The Cramér–Rao inequality.</i>
2	$I(\theta) = E[(\partial \ln p / \partial \theta)^2]$ is the Fisher information.	<i>How sharply the likelihood peaks — a flat likelihood means the data barely constrain θ.</i>
3	For N independent observations, I scales with N .	So the standard deviation falls as $1/\sqrt{N}$, and no estimator does better. Quadrupling the averaging halves the error, always.
4	For frequency estimation from N samples the bound scales as $N^{-3/2}$.	Much faster than $1/\sqrt{N}$, because a frequency error accumulates phase over the observation, so a longer observation is disproportionately informative. This is why carrier-frequency estimators improve so dramatically with preamble length.
5	An estimator that meets the bound is <i>efficient</i> .	The practical use of the bound is to know when to stop: if your estimator is within a dB of it, further cleverness is wasted and the remaining error is the physics.

Table 321. A simple frequency estimator against the Cramér–Rao bound, 2000 trials per point

Samples N	Measured σ_f	CRB	Ratio	Gap (dB)
16	0.00332	0.00183	1.812	5.165
32	0.00159	6.46×10^{-4}	2.464	7.832
64	7.70×10^{-4}	2.28×10^{-4}	3.37	10.55
128	3.95×10^{-4}	8.08×10^{-5}	4.894	13.79
256	1.91×10^{-4}	2.86×10^{-5}	6.699	16.52
512	9.77×10^{-5}	1.01×10^{-5}	9.674	19.71

The phase-difference estimator is cheap — one complex multiply and an arctangent per sample — and the ratio column says how far from optimal that cheapness leaves it. **Knowing the gap is what makes the choice informed:** a designer can then decide whether the more expensive maximum-likelihood estimator is worth its cost for this link.

Problem. Your carrier-frequency estimator is 3 dB from the Cramér–Rao bound. Is it worth improving?

Solution. Ask what the 3 dB buys downstream, not whether 3 dB is a lot. Frequency error usually enters the system as a residual phase rotation that a later tracking loop removes, so the question is whether the acquisition error is small enough for that loop to pull in, and whether the residual after pull-in meets the EVM budget. If both are comfortable, the 3 dB is free and the improvement is wasted effort. If the tracking loop's pull-in range is the binding constraint — which it often is, because pull-in range trades against loop bandwidth and therefore against jitter tolerance (Part X12) — then closing the gap directly buys acquisition reliability, which is a field-failure-rate issue and worth real hardware. **The general rule is that a bound tells you how much room is left, and only the system tells you whether the room is worth occupying.**

Problem. Why do practical receivers estimate the channel rather than use a blind equaliser, when blind methods need no training overhead?

Solution. Because training overhead is cheap and convergence risk is not. A pilot or preamble costs a known, small fraction of the throughput — a few per cent — and in exchange gives a **convex** estimation problem with a closed form, a deterministic convergence time and a verifiable result. Blind methods such as constant-modulus optimise a non-convex cost with multiple local minima; they can converge to the wrong equaliser, they converge slowly, and their convergence time depends on the data. **For a product, a bounded worst case beats a better average:** a link that occasionally takes ten times as long to acquire is a field complaint, and one that occasionally locks to a spurious solution is a returned part. Blind methods retain a real place where training genuinely cannot be inserted — monitoring an existing link, or tracking between infrequent pilots — and in those roles they are usually initialised from a trained state rather than from nothing, which converts the non-convex problem into a local one.

X26. Optimisation, the Tool Behind Every EDA Algorithm

Placement, routing, scheduling, word-length allocation, retiming, technology mapping and gate sizing are all optimisation problems, and knowing which *class* a problem belongs to tells you immediately whether a tool can solve it exactly, approximately, or not at all. That classification is the single most useful thing a hardware engineer can take from optimisation theory.

X26.1 The classification that matters

Table 322. Problem classes and what each means for a tool

Class	Solvable?	Scale	Examples in this book
Convex (LP, QP, SOCP, SDP)	Yes, to global optimality, reliably	10^5 – 10^6 variables	Gate sizing via geometric programming ; filter design with quantised constraints; buffer insertion
Integer linear (ILP)	Exactly, but exponentially in the worst case	10^3 – 10^4 for structured problems	Scheduling in HLS; technology mapping; test-pattern compaction
Submodular	Greedy gives $1-1/e$ of optimal — provably	Large	Sensor or test-point placement; coverage maximisation
Graph-structured (shortest path, max flow, matching)	Yes, polynomial	10^6 +	Maze routing, retiming, clock skew scheduling, partitioning bounds
General non-convex	Local optima only	—	Placement, analogue sizing, neural-network training
NP-hard with no structure	Heuristics	—	Placement and routing as a whole

Graduate · **The reason gate sizing is solved and placement is not.** Gate delay as a function of sizes is a *posynomial* — a sum of terms with positive coefficients and real exponents — and minimising a posynomial subject to posynomial constraints is a geometric program, which becomes convex under a logarithmic change of variables. So a million-gate sizing problem has a provable global optimum reachable in minutes. Placement has no such structure: the objective is a sum over nets of a wire-length that depends on positions in a non-convex way, and the legality constraint (no overlaps) is combinatorial. **When a tool vendor says their sizer is optimal and their placer is good, both statements are precise**, and knowing why tells you which one to argue with.

Table 323. Why complexity class decides the tool, in seconds at 10^9 operations per second

Problem size n	n^3 (s)	$n \log n$ (ms)	2^n	n^2 (ms)
10	1.000×10^{-6}	3.322×10^{-5}	1,024	1.000×10^{-4}
100	0.001	6.644×10^{-4}	$>10^{12}$	0.01
1,000	1	0.009966	$>10^{12}$	1
10,000	1000	0.1329	$>10^{12}$	100
100,000	1.000×10^6	1.661	$>10^{12}$	10000

The exponential column is the reason exact methods are confined to subproblems. An ILP over a hundred variables may solve in seconds because its structure prunes the tree; the same ILP over a hundred thousand will not solve before the product is obsolete, and no faster computer changes that.

X26.2 Convexity, and how to recognise it in your own problem

What convexity buys, and why

	Step	Justification
1	A set is convex if the segment between any two of its points stays inside.	<i>Definition.</i>
2	A function is convex if its epigraph is a convex set — equivalently, if the chord lies above the curve.	<i>Definition.</i>
3	For a convex problem, every local minimum is global.	<i>Suppose a local minimum x and a better point y; the segment from x to y is feasible and the function along it lies below the chord, so points arbitrarily close to x beat it, contradicting local minimality.</i>
4	So a descent method cannot get stuck, and a duality gap of zero gives a <i>certificate</i> of optimality.	<i>The certificate is the practical payoff:</i> you can prove to a customer that no better answer exists, rather than saying the tool stopped.
5	Convexity is preserved by non-negative sums, pointwise maxima, and composition with affine maps.	<i>These three rules are how you recognise convexity in practice</i> — build the objective from convex pieces and it is convex by construction.

Worked example 38. Recognising a convex problem in word-length allocation

Given. Minimise total multiplier area $\sum w_i^2$ subject to a noise constraint $\sum g_i 4^{-w_i} \leq \epsilon$, where $g_i > 0$ are measured noise gains from Part X1's sweep.

Method. Check each piece against the three rules: is the objective convex, is the constraint set convex, and are the variables continuous?

Objective $\sum w^2$	convex (sum of convex)
4^{-w}	convex (exponential of an affine map)
$g_i > 0$ weighting	preserves convexity
Constraint set	convex sublevel set of a convex function
Relaxed problem	convex — solvable exactly
The catch	w_i must be integers
Practical route	solve the relaxation, then round and repair — and the relaxation's value is a lower bound on the integer optimum

How this is got wrong. By throwing away the relaxation once you have rounded. The relaxed solution's cost is a bound, so it tells you how much the rounding cost and therefore whether it is worth searching harder. A greedy word-length search that reports 'we found 148 kGE' says nothing; one that reports '148 kGE against a lower bound of 141' says the search is within five per cent and can stop. **Bounds turn an open-ended search into a finished task**, which is worth more than the few per cent themselves.

Table 324. Measured relaxation gap for word-length allocation: continuous optimum, rounded up, and the slack that rounding wastes

Nodes	Continuous cost (lower bound)	Integer cost	Gap (%)	Noise used / budget
4	243.37	275	13	0.5864
8	537.67	597	11.03	0.5808
16	1358.9	1507	10.9	0.5351
32	2920.9	3292	12.7	0.4916

Solved by bisection on the Lagrange multiplier, which is exact for this separable convex problem. **The last column shows the rounding buying unwanted margin** — noise well under budget — which is the signal that a repair step (reduce the node with the best cost-per-noise trade until the budget is met) will recover most of the gap.

X26.3 Graph problems: the ones that are actually solved

Table 325. Graph algorithms an IP designer meets

Problem	Algorithm	Complexity	Where
Shortest path	Dijkstra, Bellman–Ford	$O(E \log V)$	Maze routing; timing analysis is longest path on a DAG
Longest path on a DAG	Topological order then relax	$O(V+E)$	Static timing analysis — this is the whole algorithm
Negative cycle detection	Bellman–Ford	$O(VE)$	Clock skew scheduling feasibility; retiming
Maximum flow / min cut	Push-relabel	$O(V^3)$	Partitioning, FPGA packing
Maximum matching	Hopcroft–Karp	$O(E\sqrt{V})$	Resource binding in HLS; scan chain stitching
Graph colouring	Heuristic (NP-hard)	—	Register allocation; via-layer assignment
Strongly connected components	Tarjan	$O(V+E)$	Finding the combinational loops a synthesis tool complains about

Undergraduate review · Static timing analysis is longest-path on a directed acyclic graph, and saying so demystifies it. Nodes are pins, edges are cell and net delays, and the arrival time at a node is the maximum over incoming edges of (arrival at the source plus edge delay) — computed once in topological order, in time linear in the design. That is why STA runs on a hundred million gates in minutes while simulation of the same design takes days: **STA never enumerates paths, it propagates a single number per node.** It also explains the tool's two famous characteristics. Timing is *pessimistic*, because the maximum is taken without checking whether the path is functionally sensitisable — hence false paths. And the graph must be acyclic, which is why a combinational loop makes the tool refuse or guess: there is no topological order.

Table 326. Why STA scales and path enumeration does not (10^8 graph operations per second)

Pins	Edges	One STA pass (s)	Full MMC sign-off, 36 corners (min)	Enumerating all paths
10,000	30,000	4.000×10^{-4}	2.400×10^{-4}	exponential
100,000	300,000	0.004	0.0024	exponential
1,000,000	3,000,000	0.04	0.024	exponential
10,000,000	30,000,000	0.4	0.24	exponential
100,000,000	300,000,000	4	2.4	exponential

The linear-time propagation is what makes sign-off possible at all. **The corner count of Part X2, multiplied by this, is the real sign-off cost, and it is why corner pruning is worth arguing about.**

Problem. Clock skew scheduling is posed as: choose a delay for each flop's clock so every setup and hold constraint is met. Why is this solvable exactly, when placement is not?

Solution. Because every constraint has the form $t_j - t_i \leq c_{ij}$ — a **difference constraint** — where the t are the clock arrival times and the constants come from the setup and hold inequalities of Part X2. A system of difference constraints is exactly a shortest-path problem on a constraint graph: it is feasible if and only if the graph has no negative cycle, and Bellman–Ford both decides that and produces a solution, in polynomial time. **The structure, not the size, is what makes it tractable**, and the negative cycle is even interpretable — it is a loop of flops whose combined constraints cannot be satisfied at this period, which tells you precisely which part of the design sets the frequency. Placement has no equivalent structure: its constraints couple positions in two dimensions through a non-convex objective and a combinatorial legality requirement, and no reformulation into difference constraints exists. **Recognising a problem as a system of difference constraints is worth doing deliberately**; it turns several apparently hard scheduling questions in hardware design into Bellman–Ford.

X27. Design for Test: Scan, BIST and ATPG, Worked

Test is the activity that decides whether the chips you sell work, and it is the one an IP vendor is most often asked about and least often prepared for. The arithmetic is unusually clean: coverage, pattern count, test time and defect level are all computable, and they trade against each other in ways a customer will check.

Every flop becomes observable and controllable at the cost of one multiplexer.

That single change is what makes a chip testable at all.

Figure 43. A scan chain. In test mode the multiplexers connect the flops into a shift register, so any state can be loaded and any state read out.

X27.1 Why scan, and what it costs

From an untestable machine to a testable one

	Step	Justification
1	A sequential circuit's state is reachable only through its inputs over many cycles.	<i>To test a fault deep in the state space you must first drive the machine there, which may take an unknown and enormous number of cycles.</i>
2	Test generation for sequential circuits is therefore intractable in general.	<i>The search is over input sequences, not input vectors.</i>
3	Scan converts every flop into a shift-register stage in test mode.	<i>Now any state is loadable in L shifts and any state is observable in L shifts.</i>
4	The combinational logic between flops is then testable as a pure combinational circuit.	And combinational test generation is tractable — still NP-hard, but with structure that ATPG exploits well in practice.
5	Cost: one multiplexer per flop (5–10 % area), one delay in the D path, plus routing for the chain and the enable.	The timing cost is the one that surprises: the scan mux sits in the functional data path and adds to setup time on every flop in the design.

Table 327. Scan shift time for 1000 patterns at 100 MHz shift clock

Flops	Chains	Chain length	Shift time (ms)	Extra pins
1,000	1	1,000	1000	2

Flops	Chains	Chain length	Shift time (ms)	Extra pins
1,000	8	125	125	16
1,000	32	31	31.25	64
1,000	128	7	7.8125	256
10,000	1	10,000	10000	2
10,000	8	1,250	1250	16
10,000	32	312	312.5	64
10,000	128	78	78.125	256
100,000	1	100,000	1.0000×10^5	2
100,000	8	12,500	12500	16
100,000	32	3,125	3125	64
100,000	128	781	781.25	256
1,000,000	1	1,000,000	1.0000×10^6	2
1,000,000	8	125,000	1.2500×10^5	16
1,000,000	32	31,250	31250	64
1,000,000	128	7,812	7812.5	256

Shift time is $\text{patterns} \times \text{chain length} \div \text{shift frequency}$. **Tester time is billed by the second**, so the chain count is a direct cost trade against pin count — and pins on a production tester are scarce, which is why compression exists.

Worked example 39. What scan compression buys

Given. A 1-million-flop design, 5000 patterns, 100 MHz shift clock, 32 scan pins available.

Method. Compare a plain 32-chain configuration against a compressed one that drives 200 internal chains from the same 32 pins through a decompressor.

Plain: chain length	31,250
Plain: shift cycles	156,250,000
Plain: test time at 100 MHz	1.562 s
Compressed: internal chains	200
Compressed: chain length	5,000
Compressed: test time	0.25 s
Compression ratio	6.25×
Tester cost saved at \$0.05/s over 10M units	0.6562 M USD

How this is got wrong. By evaluating compression as an area cost rather than a revenue item. The decompressor and compactor are a fraction of a per cent of area and the tester saving over a production run is measured in millions. **The constraint that limits the ratio is not area but the patterns themselves:** compression works because ATPG patterns are mostly don't-cares, and the achievable ratio is set by how many care bits a pattern has. A design with unusually constrained patterns — deep logic, many constraints — compresses less, which is a reason to talk to the test engineer during design rather than after.

X27.2 Fault models, and what each one misses

Table 328. Fault models in industrial use

Model	Assumes	Catches	Misses
Stuck-at	A node is permanently 0 or 1	Gross defects: opens, shorts to rails	Anything timing related; resistive defects
Transition / at-speed	A node is slow to rise or slow to fall	Resistive opens, weak drivers, process marginality	Needs two patterns and at-speed launch — costly
Path delay	A specific path is too slow	Marginal critical paths	Exponentially many paths — only a chosen few are tested
Bridging	Two nodes shorted	Metal defects between neighbours	Requires layout to choose realistic pairs
IDDQ	A defect draws static current	Shorts invisible to logic tests	Unusable in modern processes — leakage swamps it
Cell-aware	Defects inside a standard cell	Defects the gate-level models cannot express	Requires transistor-level analysis per cell — the library vendor must supply it

Stuck-at coverage of 99 % is not 99 % of defects, and conflating them is the commonest error in a test discussion. The stuck-at model is a convenient abstraction, not a description of physics; real defects are resistive opens and shorts whose effect is timing-dependent. A part that passes a full stuck-at suite can fail in the customer's system because a resistive via makes a path 20 % slow — a defect the model cannot express. **This is why at-speed transition testing became mandatory below about 90 nm**, and why cell-aware test was added on top. The honest statement in a datasheet is coverage *per model*, with the models named.

Table 329. Defect level against fault coverage at 85 % yield (Williams–Brown: $DL = 1 - \gamma^{1-C}$)

Coverage (%)	Yield (%)	Defect level (ppm)	Escapes per 10M units	Units per escape (thousands)
90	85	16121	1.6121×10^5	0.06203
95	85	8093	80930	0.1236
98	85	3245.1	32451	0.3082
99	85	1623.9	16239	0.6158
99.5	85	812.26	8122.6	1.231
99.9	85	162.51	1625.1	6.154

The model is the standard first-order estimate. The step from 99 % to 99.9 % coverage removes an order of magnitude of field returns, which is why automotive programmes push coverage to places that look disproportionate from a pattern-count perspective.

Figure 44. Defect level falls roughly a decade per decade of uncovered faults. The curve is why the last per cent of coverage is bought.

X27.3 BIST: testing without a tester

Table 330. Built-in self test

Kind	Mechanism	Why it exists
Memory BIST	An on-chip engine walks March algorithms through the array	Memories are most of the transistors and their faults are array-specific (coupling, retention, address decoder); a scan test cannot express them
Logic BIST	An LFSR generates pseudo-random patterns; a MISR compacts the responses	In-field self test for safety; reduces pattern storage
Repair	Spare rows and columns swapped in by fuses	Turns a failing die into a good one — Part X16's yield arithmetic
In-system test	BIST run at power-up or periodically	ISO 26262 latent-fault metric — Part X16

Worked example 40. Why random patterns alone are not enough, measured

Given. A logic block whose faults require, on average, a specific value on 12 particular inputs to be detected. Pseudo-random patterns set each input independently to 0 or 1.

Method. Compute the probability that one random pattern detects such a fault, and how many patterns are needed for high confidence — then note what happens for the hardest faults.

Probability one pattern detects	2.44×10^{-4}
Patterns for 99 % detection of that fault	18,861
If the fault needs 20 specific inputs	9.54×10^{-7}
Patterns then	4,828,869
At 100 MHz, time for those patterns	0.04829 s
Standard remedy	test points, or deterministic top-up patterns

How this is got wrong. By reporting the average and ignoring the tail. Most faults are detected by the first few hundred random patterns; a small number are random-pattern resistant and dominate the remaining coverage. The two standard responses are to **insert test points** — observation or control nodes that break the deep dependency, at a small area cost — or to follow random patterns with deterministic ATPG patterns aimed exactly at the survivors. **Both require knowing which faults survived, which means the coverage report must be read rather than summarised.**

Problem. A customer asks for your IP's fault coverage. What do you actually give them, and what do you need from them?

Solution. You cannot give a single number, and explaining why is part of the answer. Coverage depends on the customer's scan insertion, their chain configuration, their ATPG constraints and their test modes — none of which exist in your standalone block.

What you supply is testability rather than coverage: confirmation that the RTL is scan-friendly (no gated clocks without test bypass, no internally generated resets without test control, no latches, no combinational loops, no black boxes without wrappers), a list of any non-scannable elements with the reason, the test modes your block needs (memory BIST hooks, bypass for any analogue or hard macro), and any DFT constraints your block imposes on theirs. **What you need from them is their DFT strategy,** because compression, at-speed testing and any safety requirement change what the RTL must provide. **Doing this exchange at integration rather than at design is how blocks end up with untestable islands,** and a vendor who raises it unprompted is signalling experience.

X28. Caches and Coherence, Worked

Any IP block that sits behind a cache inherits its behaviour, and any block that contains one inherits its complexity. This part computes the three things that decide a cache design — the miss rate, the coherence traffic and the verification burden — because all three are routinely underestimated.

X28.1 The three Cs, measured rather than recited

Why a cache works at all

	Step	Justification
1	Programs exhibit temporal locality : a referenced address is likely to be referenced again soon.	<i>Loops, stacks, repeatedly used variables.</i>
2	And spatial locality : addresses near a referenced one are likely next.	<i>Arrays, instruction streams, structures.</i>
3	A cache exploits the first by keeping recent data and the second by fetching a whole line.	<i>The line size is the knob that trades one against the other.</i>
4	Misses classify as compulsory (first touch), capacity (working set exceeds the cache) and conflict (associativity too low).	<i>Hill's three Cs. Each has a different fix, which is why the classification is worth measuring rather than guessing.</i>
5	Compulsory misses fall with line size; conflict misses fall with associativity; capacity misses fall only with capacity.	<i>So a miss-rate problem must be classified before it can be addressed. Doubling associativity does nothing for a capacity problem, and the tool will not tell you which you have.</i>

Table 331. Measured three-Cs breakdown for a 16 kB cache (256 lines of 64 B) on two reference streams

Stream	Ways	Misses	Miss rate	Compulsory	Capacity	Conflict
mixed strided + loop	1	33,707	0.5618	16,384	17,264	59
	2	33,648	0.5608	16,384	17,264	0
	4	33,648	0.5608	16,384	17,264	0
	8	33,650	0.5608	16,384	17,266	0
four colliding arrays	1	30,000	1	256	0	29,744
	2	30,000	1	256	0	29,744
	4	256	0.008533	256	0	0
	8	256	0.008533	256	0	0

Each miss is classified by running a fully associative cache of the same capacity alongside: a miss the fully associative cache would have hit is a conflict miss. **The two streams are the two regimes.** The first is capacity-bound — it touches far more data than fits, so associativity buys almost nothing (59 conflict misses out of 33 707). The second is conflict-bound by construction: its working set is exactly the cache's capacity, so it fits, and only associativity decides whether it hits. **A miss-rate number without this breakdown cannot tell you which you have, and the two have different fixes.**

Table 332. Same 16 kB cache, 4-way, as line size is swept

Line (B)	Lines	Misses	Miss rate	Compulsory	Bytes fetched (kB)
16	1,024	33,841	0.564	16,576	528.77

Line (B)	Lines	Misses	Miss rate	Compulsory	Bytes fetched (kB)
32	512	33,713	0.5619	16,448	1053.5
64	256	33,648	0.5608	16,384	2103
128	128	16,823	0.2804	8,192	2102.9
256	64	8,411	0.1402	4,096	2102.8

The last column is the point that miss rate alone hides: **a longer line lowers the miss rate and raises the bandwidth**, because each miss moves more data. A design judged on miss rate will choose lines that are too long for the memory system it has.

X28.2 Average memory access time, and why it is the only metric

Worked example 41. Two caches, one better miss rate, and the wrong winner

Given. Cache A: 2 % miss rate, 2-cycle hit. Cache B: 1.4 % miss rate, 3-cycle hit (it is larger and more associative). Miss penalty 60 cycles.

Method. Average memory access time is hit time plus miss rate times penalty. Compute both and then find the penalty at which they cross.

Cache A AMAT	3.2 cycles
Cache B AMAT	3.84 cycles
Winner at 60-cycle penalty	A
Crossover penalty	166.7 cycles
Winner at 200-cycle penalty (DRAM)	B — 5.8 vs 6
What this depends on	the memory system, which is the customer's, not yours

How this is got wrong. By optimising the miss rate. Miss rate is a property of the cache and the workload; AMAT is a property of the whole system, and the two rank designs differently whenever the hit time changes. The crossover above is at 167 cycles, so the same two caches swap places between an SRAM-backed system and a DRAM-backed one. **An IP block containing a cache must therefore state the miss penalty its configuration was chosen for**, and ideally make the configuration a parameter, because the customer's penalty is not yours.

Table 333. The same two caches across miss penalties

Miss penalty (cycles)	AMAT A	AMAT B	Winner	Margin (%)
10	2.2	3.14	A	42.7
20	2.4	3.28	A	36.7
40	2.8	3.56	A	27.1
80	3.6	4.12	A	14.4
160	5.2	5.24	A	0.769
320	8.4	7.48	B	12.3

Computed from the definitions. **The winner changes in the middle of the range a real product spans**, which is the general reason cache parameters are made configurable rather than fixed.

X28.3 Coherence: the protocol and its traffic

Table 334. MESI states and what each permits

State	Meaning	Read hit	Write hit	On a remote read
Modified	Dirty, exclusive	Yes	Yes, silently	Write back, go to S
Exclusive	Clean, exclusive	Yes	Yes, silently — this is why E exists	Go to S
Shared	Clean, possibly shared	Yes	No — must invalidate others first	Stay S
Invalid	Not present	Miss	Miss	—

Graduate · **The E state exists entirely to make private data cheap.** Without it, a line loaded by a read would be S, and the first write to it would need a bus transaction to invalidate copies that do not exist. Since most data in most programs is private, that transaction would be pure waste on the common path. E says ‘clean and I am the only holder’, so the write is silent. The cost is that the interconnect must be able to tell a requester whether anyone else has a copy — a shared signal on a bus, or a directory lookup — which is a real structural requirement that exists solely to support this optimisation. **It is a good example of a protocol state that looks redundant on a state diagram and is load-bearing in the traffic.**

Table 335. Coherence cost against core count

Cores	Snoop messages per miss (all-to-all)	Snoops each cache must absorb	Directory bits per line (full bit vector)	Directory overhead (% of line)	Practical choice
2	2	1	2	0.3906	snoop
4	12	3	4	0.7812	snoop
8	56	7	8	1.562	snoop
16	240	15	16	3.125	directory
32	992	31	32	6.25	directory
64	4,032	63	64	12.5	directory

*Snooping broadcasts, so its traffic is quadratic in cores and every cache must absorb every other cache's misses — which becomes the bottleneck long before the wires do. A **directory is linear in traffic and pays a storage overhead**, and the crossover in practice is around eight to sixteen cores.*

Coherence is where verification cost explodes, and the reason is combinatorial. A four-state protocol with four caches has 4^4 combinations of state for one address, and the interesting bugs involve two addresses, an eviction in flight, and a request that arrives between the two halves of another transaction. The state space is far beyond directed testing, and random testing hits the interesting corners rarely. **This is the clearest case in the book for formal verification:** a coherence protocol is exactly the kind of deep, narrow state space that model checking handles and simulation does not, and proving the protocol at the specification level — before any RTL — is standard practice at companies that ship coherent systems. What formal cannot do is prove the *implementation* matches the protocol at scale, so both are needed.

Problem. Your accelerator has a private cache and the host writes its input buffer. What are the choices, and what does each cost?

Solution. Four, in increasing order of hardware and decreasing order of software burden. **Uncached access:** the accelerator does not cache the buffer at all; correct by construction, and it gives up locality entirely, which for a streaming accelerator that touches each byte once is often the right answer. **Software coherence:** the driver flushes and invalidates around each transfer; cheap in hardware, and it is a source of extremely nasty bugs because a missing invalidate is intermittent and data-dependent, and the failure appears in the customer's driver rather than in your block. **IO coherence (one-way):** the accelerator's accesses snoop the host caches but not the reverse; this is what most SoC interconnects offer today, it removes the flush burden for host-written data, and it costs interconnect support rather than accelerator complexity. **Full coherence:** the accelerator participates in the protocol as a peer, which gives the best performance for fine-grained sharing and costs a coherent cache controller plus the verification burden described above. **For a design house the recommendation is usually the third option:** it captures most of the benefit, the complexity lives in the customer's interconnect where it already exists, and it does not put a protocol state machine into your verification scope.

X29. LDPC and Polar Codes, Worked

These are the codes that reach within a fraction of a decibel of capacity and they are, between them, the error correction of 5G, Wi-Fi, high-speed Ethernet and modern storage. Their hardware is dominated by memory and interconnect rather than arithmetic, which makes them an unusually good case study in the gap between an algorithm's operation count and its silicon.

Decoding passes messages along the edges. A short cycle in this graph makes a message come back as if it were independent evidence.

Figure 45. A Tanner graph. The code is the graph; the decoder is message passing on it.

X29.1 Belief propagation, and the approximation everyone ships

From the check equation to the min-sum rule

	Step	Justification
1	A check node enforces that the XOR of its connected bits is zero.	Parity check.
2	The log-likelihood ratio of a XOR of independent bits satisfies $\tanh(L/2) = \prod \tanh(L_i/2)$.	The standard identity: probabilities of a parity multiply in the tanh domain.
3	So the exact check update is $L = 2 \tanh^{-1}(\prod \tanh(L_i/2))$.	Accurate and unimplementable: a transcendental function per edge, at hundreds of gigabits per second.
4	Because tanh saturates, the product is dominated by its smallest term.	Every factor with large $ L $ is close to ± 1 .
5	Min-sum: $L \approx (\prod \text{sgn } L_i) \cdot \min L_i $.	A comparison and a sign product — no multipliers, no tables.
6	Min-sum overestimates the magnitude, so it is scaled or offset: $\alpha \cdot \min$ or $\max(\min - \beta, 0)$.	One constant recovers most of the loss, and X29.2 measures how much.

Table 336. Measured bit error rate of a (96, $d_v=3$, $d_c=6$) LDPC code under three check-node rules, 8 iterations, 60 trials per point

SNR (dB)	Uncoded (last trial)	Plain min-sum	Scaled min-sum ($\alpha=0.75$)	Offset min-sum ($\beta=0.5$)
1	0.146	0.106	0.0767	0.0774
2	0.0625	0.0436	0.024	0.0234
3	0.104	0.00955	0.00642	0.00712
4	0.0938	0	0	0

Decoded by a direct implementation of the message-passing rules, all-ones codeword. **The scaling and offset constants cost one multiplier or one subtractor in the whole decoder and recover a measurable part of the loss; this is the cheapest improvement available in an LDPC decoder and it is universal in shipping designs.**

Graduate · Why the all-ones codeword is a legitimate test and not a shortcut. For a linear code over a symmetric channel, the error probability is independent of the transmitted codeword: the decoder's behaviour depends only on the noise realisation relative to the sent word, and the code's symmetry makes every word equivalent. So simulating the all-zero (or all-ones, under the sign convention used here) word is exact, not approximate, and it removes the encoder from the simulation entirely. **The condition to check is that the decoder is genuinely symmetric** — a quantised implementation with an asymmetric saturation or a biased rounding rule is not, and then the shortcut becomes invalid. That is a real trap in fixed-point LDPC verification and a good reason to run a full encoder at least once against the shortcut.

X29.2 Where the hardware cost actually is

Table 337. LDPC decoder memory and interconnect, 6-bit messages

Block length n	Rate	Checks m	Edges	Message memory (kB)	Message accesses per iteration
648	0.5	324	1,944	1.4238	3,888
1,944	0.5	972	5,832	4.2715	11,664
8,448	0.8	1,689	33,792	24.75	67,584
26,112	0.86	3,655	104,448	76.5	208,896

The edge count sets everything. **A decoder is a memory with comparators attached:** the message memory dominates area, and moving those messages between the variable and check phases dominates power. Arithmetic — comparisons and adds — is almost free by comparison.

Table 338. Decoder architectures

Architecture	Parallelism	Memory	Throughput	Where used
Fully parallel	Every edge has wires	Registers	Highest	Short codes; the interconnect is the limit and routing congestion sets the block length
Layered / row-parallel	One block-row of the parity matrix at a time	SRAM banks	High; roughly halves the iterations needed	The standard for 5G and Wi-Fi quasi-cyclic codes
Serial	One check at a time	Single memory	Low	Area-critical, low-rate applications
Flooding	All checks then all variables	Two message arrays	Moderate	Simple; needs about twice the iterations of layered

Undergraduate review · Why quasi-cyclic codes are the ones that get standardised. A quasi-cyclic parity-check matrix is built from circulant blocks — identity matrices shifted by a stored amount. Three consequences follow, and all three are hardware consequences rather than coding ones. The matrix is described by a small table of shift values instead of a full incidence list, so the code fits in a few hundred bytes of ROM. A whole block-row can be processed in parallel with perfectly regular addressing, because a circulant is a barrel shifter. And the same hardware serves many block lengths by changing the circulant

size, which is what lets one decoder cover a standard's whole rate and length family. **The structure exists for the decoder's benefit, at a small cost in threshold performance**, and that trade is why every modern LDPC standard is quasi-cyclic.

X29.3 Polar codes, and why they won the control channel

Channel polarisation in one page

	Step	Justification
1	Combine two uses of a channel W as $u_1 \oplus u_2$ and u_2 .	<i>The basic 2×2 transform.</i>
2	Decoding u_1 first sees a worse channel; decoding u_2 given u_1 sees a better one.	<i>The mutual information is conserved but redistributed: $I(W^-) + I(W^+) = 2I(W)$.</i>
3	Recurse n times over 2^n uses.	<i>The fraction of synthetic channels that are nearly perfect tends to $I(W)$ and the rest tend to useless.</i>
4	Put information on the good channels and freeze the rest to known values.	<i>That is the entire code construction — no search, no optimisation, and it provably achieves capacity as the length grows.</i>
5	Decoding is successive cancellation: decide bits in order, using earlier decisions.	<i>Inherently serial, which is the hardware problem; latency grows with block length even though the operation count is $N \log N$.</i>
6	Adding a CRC and keeping L candidate paths (SCL) closes most of the gap to maximum likelihood.	<i>At $L \times$ the memory and the sorting network, which is what 5G specifies for control channels.</i>

Table 339. Successive-cancellation list decoding cost

N	List size L	SC latency (cycles, unoptimised)	Path memory (bytes, 6-bit LLR)	Sorter comparisons per stage
128	1	254	96	7
128	2	254	192	14
128	4	254	384	28
128	8	254	768	56
256	1	510	192	8
256	2	510	384	16
256	4	510	768	32
256	8	510	1536	64
512	1	1,022	384	9
512	2	1,022	768	18
512	4	1,022	1536	36
512	8	1,022	3072	72
1,024	1	2,046	768	10
1,024	2	2,046	1536	20
1,024	4	2,046	3072	40
1,024	8	2,046	6144	80

Latency is the polar decoder's problem and list size is its area problem. The published architectural work is almost entirely about shortening the serial schedule — recognising sub-blocks that can be decoded in one step rather than bit by bit.

Problem. 5G uses polar codes for control channels and LDPC for data. Why not one code for both?

Solution. Because the two channels have opposite requirements and each code is better at one of them. **Control messages are short** — tens of bits — and at those lengths LDPC's performance degrades badly, because the Tanner graph cannot avoid short cycles and the asymptotic analysis that makes LDPC excellent does not apply. Polar codes with CRC-aided list decoding are close to optimal at short lengths, and their **error detection** is excellent, which matters enormously for control: a mis-decoded control message is worse than a detected failure, exactly as Part X5 argued for Reed–Solomon. **Data blocks are long and need throughput**, and there LDPC's parallel decoding wins decisively while polar's serial successive cancellation would set a latency floor. **The standard is not being indecisive; it is applying the right tool at each length**, and the lesson generalises: code choice is dominated by block length and by whether detection or throughput is the binding requirement.

X30. OFDM and MIMO, Worked

Every wireless standard of the last twenty years is OFDM, and most are MIMO. Both are, from a hardware point of view, ways of converting a hard problem into a large number of easy ones — and the conversion has costs that are computable and are the subject of most of the implementation literature.

X30.1 Why OFDM turns equalisation into division

The cyclic prefix is the whole trick

	Step	Justification
1	A multipath channel convolves the transmitted signal with an impulse response of length L .	<i>Linear convolution.</i>
2	Circular convolution in time is multiplication in the DFT domain.	<i>The convolution theorem — but only for circular convolution.</i>
3	A channel performs <i>linear</i> convolution, which is not circular, so the theorem does not apply.	<i>The blocks bleed into each other.</i>
4	Prepend the last $L-1$ samples of each block to itself.	<i>Now the tail that bleeds in is the same as what would have wrapped around, so over the retained window the linear convolution is circular.</i>
5	Therefore $Y_k = H_k X_k + N_k$, one complex multiply per subcarrier.	<i>Equalisation becomes one complex division per subcarrier</i> , replacing a time-domain equaliser of length L . This is the entire reason OFDM exists.
6	Cost: the prefix is redundancy, so the rate falls by $N/(N+L-1)$.	<i>And the peak-to-average ratio rises</i> , because a sum of many independent subcarriers is nearly Gaussian — X30.2.

Table 340. Cyclic-prefix overhead and the delay spread it tolerates

Standard	FFT size	CP samples	Rate lost (%)	Symbol duration (μs)	Max echo path (m)
802.11a	64	16	20	4	240
802.11ax	256	32	11.11	14.4	480
LTE 20 MHz	2,048	144	6.569	109.6	2160
5G NR 100 MHz SCS30	4,096	288	6.569	43.84	864

The last column is the design driver: the prefix must exceed the channel's delay spread, and delay spread is set by the environment — tens of metres indoors, kilometres in a large cell. **The prefix is therefore not a free parameter but a property of the deployment**, which is why standards define several and negotiate.

Worked example 42. Sizing an OFDM receiver's FFT from the standard

Given. 5G NR, 100 MHz channel, 30 kHz subcarrier spacing, 4096-point FFT, 14 symbols per slot, 0.5 ms slot.

Method. Compute the FFT rate the receiver must sustain, then apply Part X6's resource arithmetic to see what that implies.

Symbols per second	28000
FFT size	4,096
Complex multiplies per FFT	24,576
Complex multiplies per second	6.88×10^8
At 500 MHz, multipliers needed	2
Memory accesses per second (4 per butterfly)	2.75×10^9
SRAM ports needed at 500 MHz	6

How this is got wrong. By sizing for one FFT and forgetting the antennas and the layers. A four-antenna receiver needs four of these, and channel estimation needs more transforms again. The multiplier count is modest and the **memory port count is not** — which is Part X6's conclusion arriving in a specific product, and the reason an OFDM receiver's floorplan is dominated by buffer SRAM rather than by arithmetic.

X30.2 Peak-to-average ratio: the cost OFDM does not advertise

Table 341. Measured peak-to-average power ratio of QPSK-OFDM, 400 symbols per point

Subcarriers N	Mean PAPR (dB)	99.9th percentile (dB)	Observed max (dB)	Theoretical worst case $10\log N$ (dB)
64	6.791	9.886	9.926	18.06
256	7.893	9.95	10.03	24.08
1,024	8.78	10.93	11.04	30.1
4,096	9.469	11.87	12.26	36.12

Computed by transforming random QPSK symbols. **The theoretical worst case is never approached** — it needs all subcarriers to align in phase, which has vanishing probability — but the 99.9th percentile grows slowly and is the number the power amplifier must be backed off by.

PAPR is a power-amplifier problem, and the power amplifier is the most expensive and least efficient thing in a radio.

An amplifier must be operated below its compression point by the PAPR or the peaks clip, generating out-of-band emission that violates the spectral mask. Backing off 8 dB means operating at a small fraction of the amplifier's capability, and amplifier efficiency falls steeply with back-off — which in a handset is battery life and in a base station is the electricity bill and the cooling. **This is why PAPR reduction (clipping and filtering, tone reservation, selected mapping) and digital pre-distortion exist**, and why single-carrier FDMA was chosen for the LTE uplink: the handset's amplifier is the constraint, so the uplink gave up OFDM's convenience to get several dB of PAPR back. **An architectural decision in a standard, driven entirely by one analogue component's efficiency curve.**

Table 342. Indicative amplifier efficiency against back-off (class-AB model, 78 % peak)

Back-off (dB)	Efficiency (%)	DC power per watt of RF	Heat per watt of RF
3	55.22	1.811	0.8109
5	43.86	2.28	1.28
7	34.84	2.87	1.87
9	27.68	3.613	2.613

Back-off (dB)	Efficiency (%)	DC power per watt of RF	Heat per watt of RF
11	21.98	4.549	3.549

A first-order model, not a measurement of any particular device. **Its only job is to show the shape:** efficiency falls roughly as the voltage back-off, so every dB of PAPR costs real power, and a few dB of PAPR reduction pays for a great deal of digital signal processing.

X30.3 MIMO: capacity, and the detector that costs it

Why multiple antennas multiply capacity

	Step	Justification
1	With N_t transmit and N_r receive antennas, $\mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{n}$.	$\mathbf{H}$ is $N_r \times N_t$ complex.
2	Decompose $\mathbf{H} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^H$; the channel becomes $\min(N_t, N_r)$ parallel scalar channels with gains σ_i .	The singular value decomposition of Part X24, used as a change of basis.
3	Capacity = $\sum \log_2(1 + P_i \sigma_i^2 / N_0)$.	Sum of parallel Gaussian channels, with power allocated by water-filling.
4	So capacity grows linearly with $\min(N_t, N_r)$, not logarithmically with power.	This is the whole point: spatial multiplexing buys rate that more power cannot.
5	It requires the σ_i to be comparable — a well-conditioned $\mathbf{H}$.	Line-of-sight channels are ill conditioned and give almost no multiplexing gain. Rich scattering, which sounds like a bad channel, is what makes MIMO work — and Part X24's condition number is again the deciding quantity.

Table 343. Measured ergodic capacity at 10 dB SNR: rich scattering against pure line of sight, 400 channel realisations

Configuration	Rich scattering (bit/s/Hz)	Line of sight	Ratio	$\min(N_t, N_r)$
1×1	2.931	3.459	0.8472	1
2×2	5.618	4.392	1.279	2
4×4	11	5.358	2.054	4
8×8	21.71	6.34	3.424	8
2×4	8.036	5.358	1.5	2
4×2	6.277	4.392	1.429	2

A line-of-sight channel is rank one however many antennas it has, so its capacity does not grow with antenna count — the measurement confirms it. The second column tracks the last column, which is the linear growth the derivation predicted.

Table 344. MIMO detectors, and what each costs

Detector	Complexity	Performance	Hardware
Zero forcing	$O(N^3)$ once per channel	Poor at low SNR — noise enhancement (Part X24)	A matrix inverse
MMSE	Same	Better; regularised	Same plus a diagonal add
Ordered SIC (V-BLAST)	N passes	Noticeably better than linear	Sequential — latency grows with N ; error propagation
Sphere / K-best	Tree search, bounded	Near maximum likelihood	A sorter and a tree walk — the standard hardware compromise

Detector		Complexity	Performance	Hardware
Maximum likelihood	likeli-hood	M^{N_t} candidates	Optimal	Infeasible beyond small cases: 16-QAM 4x4 is 65 536 candidates per symbol

Problem. Why does massive MIMO make the detector *easier* rather than harder, despite having far more antennas?

Solution. Because when N_r is much larger than N_t the columns of $\mathbf{H}$ become nearly orthogonal — a consequence of concentration of measure, since independent high-dimensional random vectors are nearly orthogonal with high probability. Nearly orthogonal columns mean $\mathbf{H}^H \mathbf{H}$ is nearly diagonal, so the simple matched filter (conjugate beamforming) is nearly optimal and the noise enhancement that makes zero forcing bad at low SNR essentially vanishes. **The hard detector problem is a symptom of having barely enough antennas**, and adding antennas at the base station — where size and power are affordable — dissolves it. The cost moves elsewhere and should be named: channel estimation for many antennas needs pilot resources and becomes the limiting factor (pilot contamination), the number of RF chains dominates cost and power, and the digital front end must move enormous sample rates from the antennas to the processing. **Massive MIMO trades a detection problem for an interconnect and calibration problem**, which is a trade the digital designer should recognise as favourable and should be ready to quantify.

X31. Analogue Building Blocks, Budgeted

A digital designer does not size transistors, but does have to say whether an analogue requirement is reasonable before committing to an architecture. The quantities that answer that are few and computable: thermal noise, matching, gain-bandwidth and settling. This part gives them.

X31.1 kT/C — the noise floor you cannot design away

Why sampled noise depends only on the capacitor

	Step	Justification
1	A switch has resistance R ; its thermal noise density is $4kTR$ V^2/Hz .	<i>Johnson–Nyquist.</i>
2	The RC network's noise bandwidth is $1/(4RC)$.	<i>Integrating a single-pole response gives $\pi/2$ times the 3 dB bandwidth.</i>
3	So the sampled noise power is $4kTR \cdot 1/(4RC) = kT/C$.	The resistance cancels. A better switch does not help; only a bigger capacitor does.
4	Doubling resolution means halving the noise voltage, which means quadrupling the capacitor .	<i>And capacitance is area, and it is also the load the driver must charge, so power rises too.</i>
5	Each extra bit of a sampled system costs 4× the capacitor and roughly 4× the power.	<i>This single relation explains the shape of every converter's energy-per-conversion curve above about 10 bits.</i>

Table 345. kT/C noise and the resolution it permits (1 V full scale, 300 K)

Capacitance (fF)	RMS noise (μV)	SNR (dB)	ENOB	Approx. area (μm^2 at 2 fF/ μm^2)
10	643.58	54.8	8.81	5
100	203.52	64.8	10.47	50
1000	64.358	74.8	12.13	500
10000	20.352	84.8	13.79	5000
1.0000×10^5	6.4358	94.8	15.45	50000

Computed from kT/C alone, ignoring every other noise source, so these are optimistic. A **14-bit sampled system needs picofarads**, and the area and power that implies is why high-resolution converters are large and why oversampling architectures, which trade speed for resolution, exist.

Worked example 43. Can this ADC specification be met?

Given. A customer asks for a 16-bit, 100 MS/s SAR ADC on 1 V supply, ‘small area’.

Method. Work the kT/C requirement, then the settling requirement, then compare against what the process offers.

Required SNR for 16 bits	98.08 dB
Signal RMS at 1 V full scale	353.6 mV
Permitted noise RMS	4.41 μV
Required capacitance	212.96 pF
Array area at 2 fF/ μ m ²	1.0648$\times 10^5$ μm²
Settling time available at 100 MS/s, 16 SAR cycles	625 ps
Time constants needed for 16-bit settling	11.09
Required RC	56.36 ps
Verdict	the capacitor and the settling requirement are in direct conflict

How this is got wrong. By treating ‘16-bit’ and ‘100 MS/s’ as independent requirements. The noise requirement forces a large capacitor; the speed requirement forces that capacitor to settle in picoseconds, which forces a very low switch resistance and therefore an enormous switch, which loads the previous stage. This is why 16 bits at 100 MS/s is a time-interleaved or pipelined architecture and not a single SAR, and why the answer to the customer is a **question about their actual SNR requirement in the signal band** — if they need 16 bits over 1 MHz rather than over 50 MHz, oversampling changes the arithmetic completely.

X31.2 Matching: why analogue area is set by statistics

Pelgrom's law

	Step	Justification
1	Threshold voltage varies between nominally identical devices because of random dopant fluctuation and line-edge roughness.	<i>A counting phenomenon: fewer dopants under a smaller gate means larger relative variation.</i>
2	The standard deviation of the mismatch between two devices is $\sigma_{\Delta V_{th}} = A_{VT}/\sqrt{WL}$.	<i>Pelgrom's law, verified across many processes. A_{VT} is a process constant of a few mV$\cdot\mu$m.</i>
3	So halving the mismatch requires four times the area.	<i>The same 4$\times$ law as kT/C, arriving from a completely different mechanism.</i>
4	A comparator's input-referred offset is this mismatch; a current mirror's error is proportional to it.	<i>Which sets the minimum size of every matched pair in a converter.</i>
5	Digital calibration converts area into computation.	<i>Measure the offset once, store it, subtract it. This is the dominant trend in mixed-signal design and the reason the digital content of converters keeps growing.</i>

Table 346. Pelgrom matching against device area ($A_{VT} = 3.5$ mV $\cdot\mu$ m)

WL (μm^2)	$\sigma_{\Delta V_{th}}$ (mV)	3σ spread (mV)	Bits resolvable without calibration at 1 V FS	Pair area (μm^2)
0.01	35	210	2.252	0.02
0.1	11.07	66.41	3.913	0.2
1	3.5	21	5.573	2
10	1.107	6.641	7.234	20
100	0.35	2.1	8.895	200

Without calibration, matching alone limits an uncalibrated comparator to about eight bits at sane areas. Every converter above that resolution calibrates, and the calibration engine is digital — which is how a digital designer ends up owning a large part of an analogue block.

Graduate · The calibration trade, stated as arithmetic. Suppose a comparator needs 1 mV of offset. Pelgrom says that costs about $12 \mu\text{m}^2$ of gate area per device, and in a 64-way time-interleaved ADC that is repeated 64 times, in the fastest and most power-hungry part of the chip. Alternatively, build a minimum-size comparator with 10 mV of offset and add a trim DAC plus a digital loop that measures and cancels it. The trim DAC is small, the loop is a counter and a comparator, and the whole thing is synthesised. **The crossover is far to the digital side and moves further every process node**, because digital area shrinks and A_{VT} improves only slowly. This is the single clearest instance of the general trend this book keeps meeting: **buy analogue precision with digital computation.**

X31.3 Gain, bandwidth and settling

Table 347. What a resolution demands of an amplifier

Bits	Settling accuracy	Time constants needed	Minimum open-loop DC gain (dB)	Settling in units of 1/GBW
8	0.00195	6.238	54.19	0.9929
10	4.88×10^{-4}	7.625	66.23	1.213
12	1.22×10^{-4}	9.011	78.27	1.434
14	3.05×10^{-5}	10.4	90.31	1.655
16	7.63×10^{-6}	11.78	102.4	1.875

*Static accuracy needs loop gain (finite gain leaves a proportional error); dynamic accuracy needs time constants. **16-bit accuracy needs about 100 dB of DC gain and twelve time constants**, and those two requirements fight each other because high gain means more stages means more poles means harder compensation.*

Table 348. The analogue specifications a digital architect should be able to sanity check

Quantity	Rule of thumb	If the requirement exceeds it
Sampled SNR	kT/C ; 14 bits needs $>1 \text{ pF}$ at 1 V	Oversample, or relax full scale, or use a different architecture
Uncalibrated comparator offset	Pelgrom; ~ 8 bits at sensible area	Add digital calibration
Amplifier DC gain	$\sim 6 \text{ dB per bit}$	Gain boosting, or a correlated-double-sampling scheme
Aperture jitter	$\text{SNR} = -20 \log(2\pi f_{in} \sigma_t)$ — Part X12	A better clock, not a better converter
Reference noise	Appears directly at the output	Filter it; and remember the filter capacitor is area too
Supply rejection	Falls with frequency; poor above the loop bandwidth	This is why the PDN of Part X32 matters to analogue blocks

Problem. Your digital block shares a supply with an ADC and the customer reports spurs at your clock frequency. Whose problem is it?

Solution. Both of yours, and the useful response is to find out which mechanism rather than which party. There are three paths and they are distinguishable by measurement. **Supply coupling:** your switching current modulates the shared rail, and the converter's finite power-supply rejection turns that into an input offset; test by changing your block's activity and watching whether the spur amplitude tracks, and by separating the supplies if the board permits. **Substrate coupling:** switching current injects into the substrate and reaches the converter's sensitive nodes; this is layout, and the remedies are guard rings, deep n-well isolation and distance. **Clock coupling:** your clock capacitively couples into the sampling network, which is the worst of the three because it lands exactly at a fixed frequency and its harmonics. **The digital side's contribution, and it is a real one, is to reduce di/dt :** spread the clock tree's switching with deliberate skew, gate clocks aggressively so the average current is lower, add on-chip decoupling, and avoid large simultaneous switching events. **None of that is exotic, and all of it is far cheaper than asking the analogue designer for another 20 dB of supply rejection,** which may not be available at any price.

X32. The Power Delivery Network, Worked

Every timing number in Part X2 assumed a supply voltage. The network that delivers it is a distributed RLC structure whose impedance must be low across six decades of frequency, and when it is not, the result is a voltage droop that shows up as a timing failure nobody can reproduce. This is a digital designer's problem even though it looks like an analogue one.

Each stage covers a different decade of time.
A gap between two of them is an impedance peak, and an impedance peak is a droop.

Figure 46. The power delivery hierarchy. Each element handles a different timescale because each is limited by its own parasitic inductance.

X32.1 Target impedance, and where the number comes from

From a droop budget to an impedance specification

	Step	Justification
1	The supply must stay within $\pm\delta$ of nominal for the timing libraries to apply.	<i>Typically 5 %. Outside it, the delays are not the ones you signed off with.</i>
2	A current step ΔI produces a voltage $Z(f)\Delta I$.	<i>Ohm's law for an impedance.</i>
3	Target impedance $Z_t = \delta V_{dd} / \Delta I_{max}$.	<i>The one number the whole PDN is designed to, and it must be met at every frequency, not on average.</i>
4	ΔI_{max} is the worst-case step, not the average current.	<i>A clock-gated block waking up, or a test pattern that toggles everything, is a far larger step than any functional average — which is why maximum-toggle test patterns can fail a part that works in its application.</i>
5	Falling voltage and rising current per node make Z_t shrink every generation, quadratically.	<i>This is why PDN design has become progressively harder rather than benefiting from scaling.</i>

Table 349. Target impedance across process generations (5 % droop budget)

Node	V_{dd} (V)	Peak current (A)	Z_t (m Ω)	Peak power (W)	Droop budget (mV)
180 nm	1.8	2	45	3.6	90
90 nm	1.2	10	6	12	60
28 nm	1	40	1.25	40	50
7 nm	0.8	120	0.3333	96	40
5 nm	0.75	250	0.15	187.5	37.5

The current figures are indicative of a large SoC at each generation rather than any specific part. **The impedance target falls by more than two orders of magnitude across the table**, which is why on-die decoupling and integrated voltage regulators appeared.

Worked example 44. Sizing on-die decoupling capacitance

Given. A block draws 5 A when active and is clock-gated. On wake-up the current rises in 2 ns. The package inductance is 100 pH and the droop budget is 40 mV.

Method. The package cannot supply current faster than its inductance allows, so on-die capacitance must cover the interval until the package catches up. Compute the charge needed and hence the capacitance.

Current step	5 A
Rise time	2 ns
$L di/dt$ if the package had to supply it	250 mV
Droop budget	40 mV
Verdict	the package alone exceeds the budget by 6×
Charge to supply during the step	5 nC
Capacitance for a 40 mV droop	125 nF
Area at 10 fF/ μm^2 (MOS cap)	12.5 mm ²

How this is got wrong. By budgeting only the resistive drop. At a nanosecond timescale the package is an inductor, not a wire, and $L di/dt$ dominates the static IR term by a large factor. **The remedy is not lower resistance but local charge storage**, and the area it costs is real — on-die decoupling is commonly several per cent of die area and in some designs more than ten. A second, cheaper remedy belongs to the digital designer: **ramp the current instead of stepping it**, by staging the clock-gate release across several cycles, which is a few gates of logic and can reduce the required capacitance by a large factor.

X32.2 Resonance: the peak that puts the droop where you are not looking

Table 350. Resonant peaks formed by each inductance with the capacitance below it

L (pH)	C (nF)	R (mΩ)	Resonant frequency (MHz)	Q	Peak impedance (mΩ)
1000	100	5	15.915	20	100
1000	1000	5	5.0329	6.325	31.62
100	100	2	50.329	15.81	31.62
100	10	2	159.15	50	100
10	100	1	159.15	10	10

Every inductance in the hierarchy resonates with the capacitance on the load side of it, and at resonance the impedance is Q times the series resistance. **A high- Q peak is the dangerous case:** if the current spectrum has energy there, the droop is far worse than the target impedance suggests.

The first-droop, second-droop, third-droop language engineers use is just this resonance hierarchy, and the dangerous one is usually the mid-frequency droop. The first droop (hundreds of megahertz) is handled by on-die capacitance; the third (kilohertz) by the regulator's control loop. The second — tens to a couple of hundred megahertz, set by package inductance against on-die capacitance — sits in a gap between the two remedies and is where the highest- Q peak usually lands. **It is also, unhelpfully, right where a processor's activity changes:** a loop that alternates between a heavy and a light phase at that rate excites it directly, which is the origin of the classic 'this benchmark fails and that one does not' report. The digital remedies are to add damping (series resistance in some decoupling, deliberately), to spread activity in time, and to use an adaptive

clock that stretches the period when a droop is detected — which converts a functional failure into a small performance loss and is now common in large processors.

X32.3 Electromigration and the static budget

Table 351. Current a wire can carry before electromigration limits its life (indicative 1.5×10^6 A/cm², 0.2 μ m thick)

Width (μ m)	Cross-section ($\times 10^{-8}$ cm ²)	Max current (mA)	mA per μ m of width	Resistance per μ m length ($\mu\Omega$)
0.1	0.02	0.3	3	2.2000×10^5
0.2	0.04	0.6	3	1.1000×10^5
0.5	0.1	1.5	3	44000
1	0.2	3	3	22000
2	0.4	6	3	11000

Indicative constants, not a PDK. The useful content is the third column: a few milliamps per micron of width is the order of magnitude, so a 5 A block needs of the order of a millimetre of total metal width to feed it — which is why power grids are wide, numerous and on the thick upper metal layers.

Problem. Your block passes timing in every corner and fails intermittently in silicon at high activity. How do you decide whether it is the PDN?

Solution. Look for the signature, which is specific and distinguishable. **A PDN-induced failure is activity dependent rather than pattern dependent:** it appears when many things switch at once, not when a particular logical case occurs, so a test that toggles a lot fails while a functionally harder but quieter test passes. **It moves with supply and with frequency in a particular way:** raising the supply helps more than it should for a simple timing problem, because it increases the margin against droop as well as speeding the logic. **It correlates with di/dt, not with average power,** so a test with the same average current but smoother activity passes. The measurements that settle it are an on-die droop monitor if one exists — and if none exists, that is the lesson for the next design, because a ring-oscillator-based droop detector is a few hundred gates — and an experiment that staggers the wake-up of the block's clock-gating domains, which changes only di/dt. **If staggering fixes it, the PDN is the cause and the cheapest fix is the staggering you just used to diagnose it.**

X33. Boolean Reasoning: BDDs, SAT and Equivalence Checking

Three tools an IP designer uses every week — logic equivalence checking, formal property verification and automatic test pattern generation — are the same engine underneath: a decision procedure for Boolean formulas. Knowing what that engine can and cannot do explains why one proof finishes in seconds and another never finishes, which is otherwise the most frustrating thing about these tools.

X33.1 Representations, and why the choice is everything

Table 352. Ways to represent a Boolean function

Representation	Size	Equivalence check	Where it is used
Truth table	2^n always	Trivial	Small cells; library characterisation
Sum of products	Can be exponential	Hard	Two-level minimisation, PLAs
BDD (reduced, ordered)	Canonical — and variable-order dependent	Pointer comparison	Symbolic model checking; some equivalence checking
AIG (and-inverter graph)	Linear in the circuit	Needs a solver	The working representation of every modern synthesis and verification tool
CNF for SAT	Linear via Tseitin encoding	NP-complete, and fast in practice	Formal verification, ATPG, equivalence

Graduate · **Canonicity is the property that makes BDDs both magical and fragile.** Two functions are equal if and only if their reduced ordered BDDs are the identical graph, so equivalence is a pointer comparison rather than a search. The price is that the size depends catastrophically on the variable order: the same function can be linear under one order and exponential under another, and finding the best order is itself NP-hard. The canonical example is a multiplier, whose BDD is exponential under *every* order — which is exactly why BDD-based equivalence checking fails on datapaths and why modern tools use AIGs plus SAT instead. **When a tool reports that it is ‘building BDDs’ and then runs out of memory, this is what happened,** and the remedy is a different engine rather than a bigger machine.

Table 353. Measured decision-diagram size for $x_0y_0 + x_1y_1 + \dots$ under two variable orders

Variables	Product terms	Interleaved order (nodes)	Separated order (nodes)	Ratio
4	2	4	6	1.5
8	4	8	30	3.75
12	6	12	126	10.5
16	8	16	510	31.88

Built by exhaustive construction with subfunction sharing, which is what reduction does. **The interleaved column is exactly n ; the separated column is $2^{n/2+1}-2$.** Linear against exponential, on the same function with the same tool. The ratio is modest at these sizes because the exponent is small — at 40 variables it is a factor of 52 000 — $(2^{21}-2)/40$ — which is the difference between a second and a week. This is the whole of BDD practice in one table.

X33.2 Why SAT is fast even though it is NP-complete

What a modern SAT solver actually does

	Step	Justification
1	Convert the circuit to CNF by Tseitin encoding: one variable per gate, a few clauses per gate.	<i>Linear in circuit size — no blow-up here, unlike naive expansion.</i>
2	Search by assigning variables, propagating implications, and backtracking on conflict.	<i>DPLL. The naive version is hopeless.</i>
3	On conflict, derive a new clause that explains it (clause learning) and add it.	<i>This is the single change that made SAT practical. The learned clause prunes an entire region of the search space, not just the current branch.</i>
4	Backjump non-chronologically to the level the conflict actually came from.	<i>Rather than undoing one decision at a time.</i>
5	Restart periodically, keeping the learned clauses.	<i>Escapes a bad region of the search while retaining what was learned.</i>
6	Result: industrial instances with millions of variables solve in seconds , while small random instances at the hardness threshold do not.	<i>Structure, not size, decides. Circuits have enormous structure; that is why circuit problems are the easy case and why a tool's runtime is unpredictable in the specific way engineers observe.</i>

Worked example 45. Why equivalence checking succeeds where simulation cannot

Given. Comparing a 64-bit multiplier's RTL against its gate netlist.

Method. Compare the exhaustive-simulation cost with what an equivalence checker does instead.

Input space	2^{128}
Vectors per second, simulated	10^7
Time to simulate exhaustively	$>10^{23}$ years
What an equivalence checker does	proves the two are equal for all inputs
How	structural matching of internal points, then SAT on each cone
Why it works	the two designs share almost all their internal structure
When it fails	after retiming, resource sharing, or a datapath rewrite — the structure no longer matches

How this is got wrong. By assuming equivalence checking always works. It works because it finds internal equivalence points and cuts the problem into small cones; a transformation that destroys that correspondence — retiming across register boundaries, sequential optimisation, a multiplier architecture change — leaves the tool with one enormous cone and it fails. **The practical consequence is a rule for the synthesis flow:** turn on transformations that break equivalence checking only when you are prepared to verify the result another way, and know which ones they are before the schedule depends on them.

Table 354. Why cone size, not design size, decides an equivalence check

Situation	Cones	Typical cone size (gates)	Total gates	Difficulty
Control logic	50,000	40	2,000,000	easy

Situation	Cones	Typical cone size (gates)	Total gates	Difficulty
Datapath adders	2,000	200	400,000	easy
Multiplier (structural match)	500	2,000	1,000,000	easy
Multiplier (after rewrite)	1	500,000	500,000	the hard case

Illustrative structure counts. The last row has the same total size and is the one that does not finish, because the work per cone grows far faster than linearly.

X33.3 Model checking: proving something about all time

Bounded model checking, and what 'bounded' costs

	Step	Justification
1	Unroll the design's transition relation k times.	<i>Copy the combinational logic k times, chaining state.</i>
2	Assert the initial state and the negation of the property.	<i>If satisfiable, the assignment is a counterexample trace of length $\leq k$.</i>
3	Hand the whole thing to SAT.	A bug of depth $\leq k$ is found; a bug of depth $k+1$ is not.
4	So BMC is a very good bug hunter and not a proof .	<i>This is the distinction that matters when reading a tool's report: 'proven to depth 40' is not 'proven'.</i>
5	A full proof needs induction, interpolation or IC3/PDR, which find an inductive invariant.	These do give unbounded proofs , and they are what a tool means by 'proven' without a depth.
6	The bound needed for confidence is the design's <i>diameter</i> — how many cycles to reach any reachable state.	<i>Usually unknown, and for a design with a large counter it is astronomically large. Which is why counters are abstracted before proving anything around them.</i>

The three ways a formal proof lies to you, in order of frequency. **Over-constraint:** an assumption excludes the input that would have failed, so the property is proven about a machine that is not yours. This is the formal equivalent of a disabled checker and is by far the commonest; the defence is to check that the constraints are satisfiable together with interesting behaviour, which good tools report as 'assumption coverage'. **Vacuity:** the property's antecedent never occurs, so it holds trivially — 'if a grant is given without a request...' proven because no grant is ever modelled. **A bounded result read as a proof**, as above. **All three report green**, which is why this book's rule applies with full force here: a proof whose assumptions have not themselves been checked is an unexamined green light.

Problem. Where should a design house spend its formal effort, given that it cannot afford to prove everything?

Solution. On the properties whose failure is catastrophic and whose state space is deep and narrow, which is where formal has the advantage over simulation. In practice that means, in order: **arbiters and any structure that can starve**, because starvation is a liveness property and simulation can never prove its absence; **FIFOs, credit counters and flow control**, where overflow and underflow are provable and the bugs appear only at full rate; **protocol interfaces**, where a vendor-supplied assertion set exists and proving compliance at the boundary is worth more than any amount of traffic; **clock-domain crossing structures**, where the interesting cases are timing-related and simulation is blind to them; and **security properties**, where the question is whether information can flow between two places and the answer must hold for all inputs. **What not to spend it on: datapath equivalence at the algorithm level** — a bit-exact reference model plus random simulation gets there faster — **and anything with a large counter in the cone**, until the counter has been abstracted.

X34. Logic Synthesis: What the Tool Is Actually Doing

Synthesis is the step an IP designer has least visibility into and most dependence on. Its behaviour is not arbitrary: it is a sequence of well-defined transformations with known strengths, and knowing them turns ‘the tool did something odd’ into a specific diagnosis.

X34.1 The pipeline, stage by stage

Table 355. What each synthesis stage does and what it cannot do

Stage	Input → output	Optimises	Cannot
Elaboration	RTL → generic netlist	Nothing — it interprets the language	Fix a coding style that infers a latch
Datapath extraction	Operators → architectures	Picks adder and multiplier structures from a library	Restructure an algorithm you wrote out by hand as gates
Technology-independent optimisation	Generic netlist → smaller generic netlist	Factoring, common subexpressions, constant propagation, redundancy removal	Know anything about delay in picoseconds
Technology mapping	Generic → library cells	Covers the network with cells at minimum cost — solvable optimally on a tree	Change the network's structure much
Timing-driven restructuring	Netlist → netlist	Balances the critical path, duplicates, remaps	Buy more than a limited amount — see Part X2
Sizing and buffering	Netlist → sized netlist	Convex, near-optimal (Part X26)	Fix a structural problem

Graduate · **Technology mapping is optimal on trees and heuristic on graphs, and that single fact explains most of what a synthesis tool does well.** The classic formulation covers a Boolean network with library cells at minimum cost. If the network is a tree, dynamic programming over the nodes gives a provably optimal cover in linear time. Real networks are DAGs with reconvergent fanout, so the tool partitions them into trees at multiple-fanout points, maps each optimally, and accepts that the partition itself was a heuristic choice. **The practical consequence is that logic with heavy reconvergence maps worse than logic without it,** and that restructuring an expression to reduce fanout — which looks cosmetic in RTL — can measurably change the result.

Table 356. A balanced tree of two-input gates: the structure mapping likes

Depth	Gates	Logic levels	DP table entries (4 cells/node)	Gate delays at 2 per level
2	3	2	12	5
4	15	4	60	9
6	63	6	252	13
8	255	8	1,020	17
10	1,023	10	4,092	21
12	4,095	12	16,380	25

*Dynamic-programming mapping visits each node once per candidate cell, so it is linear in gates times library size. **This is why mapping a million-gate design takes minutes** even though the underlying covering problem is NP-hard on general graphs.*

X34.2 What your RTL controls, and what it does not

Table 357. RTL constructs and what the tool does with them

You write	The tool produces	You control it by
<code>a + b</code>	An adder chosen from an architecture library	The timing constraint — not by writing the adder yourself
<code>a * b</code>	Booth or array multiplier, possibly shared	Constraints, and <code>set_dont_use</code> if the choice is wrong
<code>case</code> (full)	A multiplexer tree	Ordering and priority annotations
<code>case</code> (incomplete, no default)	A latch — almost never what you meant	Write the default; lint for it
<code>if</code> chain	Priority logic — deep and slow	Use <code>case</code> when the conditions are mutually exclusive
A for loop	Unrolled combinational logic	The loop bound; there is no hardware loop
<code>x <= y</code> in a clocked block	A flip-flop	—
Division by a variable	A large slow divider	Do not; see Part X9
Division by a constant	Shifts and adds	Nothing needed — the tool does this well

Worked example 46. The cost of an if-chain that should have been a case

Given. A 16-way priority `if/else if` chain versus a 16-way `case`, each selecting between 16 values.

Method. Count the logic levels. A priority chain is a serial selection; a `case` is a balanced tree, because the tool knows the conditions are mutually exclusive.

Priority chain: multiplexers in series	16
Delay at ~2 gate levels per 2:1 mux	32 gate levels
Case: mux tree depth	4
Delay	8 gate levels
Ratio	4×
At 25 ps per gate level	800 ps vs 200 ps
Period this costs at 1 GHz	60 % of it, for nothing

How this is got wrong. By assuming the tool will notice the conditions are exclusive. Sometimes it does, and it cannot in general — proving exclusivity is a Boolean problem it does not always attempt. Writing `case`, or annotating the chain as parallel, tells it directly. **This is the single highest-value RTL coding habit for timing**, and it costs nothing; a priority structure should appear only where priority is actually meant, and then the depth is a deliberate cost rather than an accident.

X34.3 Retiming: moving registers without changing behaviour

Why retiming is a graph problem with an exact answer

	Step	Justification
1	Model the circuit as a graph: nodes are combinational blocks with delay, edges carry a register count.	<i>The standard retiming model.</i>
2	Retiming assigns each node an integer r_v : move r_v registers from its outputs to its inputs.	<i>Registers on edge (u,v) become $w + r_v - r_u$.</i>
3	Legality requires every edge to keep a non-negative count: $r_u - r_v \leq w$.	A system of difference constraints — exactly the structure Part X26 identified as solvable.
4	Achieving period P adds more difference constraints between node pairs.	<i>Derived from the longest combinational path between them.</i>
5	So ‘is period P achievable by retiming?’ is a negative-cycle test, and binary search over P finds the optimum.	Polynomial, exact, and implemented in every synthesis tool.
6	What it cannot do: change the number of registers on any cycle.	The latency around a feedback loop is invariant under retiming , which is why retiming cannot fix a loop that is too long — Part X4’s DFE problem is exactly this, and the answer there was unrolling, which changes the graph.

Retiming is exact and is nevertheless often turned off, for reasons worth knowing. It renames and moves registers, which breaks the structural correspondence equivalence checking depends on (Part X33), so verification becomes sequential equivalence checking — a much harder problem that may not complete. It also destroys the correspondence between RTL signal names and netlist nodes, which makes debug and ECOs painful, and it can interact badly with scan insertion and with clock gating. **The common compromise is to retime within a clearly delimited pipeline and to verify that block by simulation against its pre-retiming version**, rather than enabling it design-wide.

Problem. Synthesis reports your block at 620 MHz against a 700 MHz target. List what you would try, in order of cost.

Solution. Cheapest first, because the early items often suffice. **Check the constraints before the design:** an over-constrained input delay, a missing multicycle path, or a clock defined without its uncertainty will each produce a believable-looking failure that no RTL change fixes. **Read the critical path and classify it** — if it crosses a whole datapath it is structural, if it is a long priority chain it is X34.2, if it starts or ends at a boundary it is a constraint issue, and each has a different fix. **Try the free restructuring:** turn an if-chain into a case, split a wide comparison, move a constant multiplication to a shift-add, precompute something that depends only on slowly changing inputs (Part X9’s rule). **Then pipeline** — one more stage, which costs latency and a verification change and is usually decisive. **Then re-architect:** parallel slices at a lower rate, which is Part X7’s energy argument arriving as a timing fix. **What not to do first is instantiate gates by hand;** it is slow, it does not port, and the tool is better at it than you are except in the rare case where you know something it cannot — and then you should be telling it, through a constraint, rather than bypassing it.

X35. Hardware Data Structures: CAM, Hashing and Bloom Filters

Networking, storage and security IP spend most of their logic looking things up. The structures that do it are a small, well-understood family with sharply different cost profiles, and choosing among them is one of the clearest cases in this book where an architectural decision is settled by arithmetic rather than by preference.

X35.1 The lookup family

Table 358. Lookup structures compared

Structure	Query	Area per entry	Power	Updates	Used for
RAM (direct index)	1 cycle	1 bit/bit	Low	1 cycle	Small, dense key spaces
Binary CAM	1 cycle, all entries in parallel	~8–10 transistors per bit	Very high — every cell compares every cycle	1 cycle	MAC address tables, tag matching
Ternary CAM	1 cycle, with don't-cares	~16 transistors per bit	Higher still	Needs priority ordering — insertion can require moving entries	Longest-prefix routing, ACLs
Hash table	1–2 cycles typical	~1 bit/bit plus load factor	Low	1 cycle, except on collision	Flow tables, caches
Cuckoo hash	<i>d</i> parallel probes, worst case bounded	~1.05 bits/bit at high load	Low	Insertion can cascade	Flow tables where a bounded query time is required
Trie / tree	log <i>n</i> memory accesses	Pointer overhead	Low	Simple	Prefix matching in software
Bloom filter	<i>k</i> probes	~10 bits per entry for 1 % false positive	Low	Insert only	A cheap pre-filter in front of an expensive lookup

Graduate TCAM is the structure that decides the cost of a router, and it is worth knowing why it is so expensive. A ternary cell stores three states — 0, 1 and don't-care — which needs two storage bits plus comparison logic, roughly sixteen transistors against six for SRAM. Worse, every cell compares on every lookup, so power is proportional to the whole table rather than to the entry found: a large TCAM can dissipate tens of watts doing nothing but matching. **The architectural responses all reduce the number of cells that must compare** — partition the table by prefix length and activate only relevant banks, put a small filter in front, or replace TCAM with an algorithmic trie in SRAM and accept multiple accesses. Every high-end switch datasheet's power figure is substantially a statement about this one structure.

Table 359. TCAM cost against table size, 144-bit keys (indicative 16 T/cell against 6 T SRAM, 1 GHz lookup)

Entries	Key bits	SRAM-equivalent (MB)	TCAM area as SRAM-equivalent (MB)	Match-line power (W, indicative)
1,000	144	0.01717	0.09155	1.728×10^{-4}
10,000	144	0.1717	0.9155	0.001728
100,000	144	1.717	9.155	0.01728
1,000,000	144	17.17	91.55	0.1728

Indicative constants, not a vendor datasheet. The shape is the point: area roughly five times SRAM for the same bits, and a power term that grows with table size independently of the traffic.

X35.2 Hashing: the birthday problem decides your table size

Why a hash table needs to be much larger than its contents

	Step	Justification
1	With n items in m buckets, the probability that a particular pair collides is $1/m$.	<i>Uniform hashing assumption.</i>
2	There are $n(n-1)/2$ pairs, so the expected number of colliding pairs is about $n^2/(2m)$.	<i>Linearity of expectation.</i>
3	Collisions start appearing when $n \approx \sqrt{m}$, not when $n \approx m$.	<i>The birthday paradox. This is the fact that surprises people sizing tables.</i>
4	The longest chain with $n = m$ is $\Theta(\log n / \log \log n)$ — about 5–8 for realistic sizes.	<i>So a single-probe hardware lookup fails often enough to matter.</i>
5	Two hash functions and a choice of the emptier bucket reduces the longest chain to $\log \log n$.	<i>The power of two choices: an exponential improvement from one extra probe. This is why hardware hash tables are multi-way.</i>

Table 360. Measured longest bucket in a 4096-bucket table, one hash against two-choice hashing, 30 trials per point

Load factor	Keys	Longest bucket, 1 hash	Longest bucket, 2 choices	Ratio
0.25	1,024	3.5	2.1	1.667
0.5	2,048	4.367	3	1.456
0.75	3,072	5.5	3.4	1.618
0.9	3,686	6.133	3.9	1.573
0.95	3,891	6.2	4.033	1.537

Simulated with random keys, seed 13. The second hash roughly halves the worst bucket at every load, which in hardware is the difference between a lookup engine that must handle eight-deep chains and one that handles four.

Worked example 47. Sizing a flow table for a bounded lookup time

Given. A network block must look up 200 000 flows at 100 Gbit/s, one lookup per 64-byte packet, with a *bounded* lookup time of two memory accesses.

Method. Bounded worst case rules out chaining. Compute what a 4-way cuckoo table costs at a load factor it can sustain.

Packet rate at 64 B	148.8 Mpps
Lookups per second	1.49×10^8
Flows	200,000
Cuckoo load factor achievable at 4 ways	0.97
Buckets needed	206,185
Entries at 4 per bucket	206,184
Memory at 64 B per entry	12.58 MB
Probes per lookup	4 (parallel, one bucket read)
Worst-case accesses	2

How this is got wrong. By choosing the average-case structure for a worst-case requirement. Chained hashing has a superb average and an unbounded tail, and a networking datapath is judged on the tail: a lookup that occasionally takes eight accesses either stalls the pipeline or drops the packet. **Cuckoo hashing buys a bounded query at the cost of a potentially long insertion**, which is the right trade because insertions are rare and can be handled by a slow path. Recognising which operation must be bounded is the whole of the design decision.

X35.3 Bloom filters: paying memory for certainty in one direction

The false-positive rate, and the optimal number of hashes

	Step	Justification
1	A Bloom filter is m bits; inserting an item sets k bits chosen by k hashes.	<i>No item is stored — only its fingerprint in the bit array.</i>
2	After n insertions, the probability a given bit is still zero is $(1-1/m)^{kn} \approx e^{-kn/m}$.	<i>Independent settings.</i>
3	A query gives a false positive when all k bits happen to be set: $p = (1-e^{-kn/m})^k$.	Never a false negative — that asymmetry is the whole value.
4	Minimising over k gives $k = (m/n) \ln 2$.	<i>And then $p = 2^{-k}$.</i>
5	So about $1.44 \log_2(1/p)$ bits per item, regardless of how large the items are.	<i>A 1 % filter costs about 10 bits per item whether the items are 32-bit or 1500-byte. That independence from key size is why it is used in front of expensive lookups.</i>

Table 361. Bloom filter false-positive rate against bits per item

Bits/item	Optimal hashes k	False positive	(%)	Memory for 10^6 items (MB)
4	3	0.147	14.7	0.4768
8	6	0.0216	2.16	0.9537
10	7	0.00819	0.819	1.192

Bits/item	Optimal hashes k	False positive	(%)	Memory for 10^6 items (MB)
12	8	0.00314	0.314	1.431
16	11	4.59×10^{-4}	0.0459	1.907
20	14	6.71×10^{-5}	0.00671	2.384

Computed from the closed form. **Ten bits per item buys about one per cent**, and each further factor of ten costs about 3.3 bits — a very good rate of exchange when the alternative is storing the keys.

Problem. Where does a Bloom filter belong in an IP block, and where does it not?

Solution. It belongs wherever a **negative answer is common and an expensive lookup can be skipped**, and where a false positive costs only wasted work rather than a wrong result. Concretely: in front of a TCAM or an off-chip table, to avoid the access entirely for the majority of keys that are absent; in a cache to avoid probing a way; in a coherence directory to avoid a snoop. In each case the filter is an optimisation and the real structure still answers. **It does not belong anywhere the answer is used directly**, because a false positive is then a wrong answer — and it does not belong where deletions are needed, because a plain Bloom filter cannot delete (clearing a bit may un-insert another item); that needs a counting Bloom filter at four times the memory, and at that point a small hash table is often better. **The design question to ask is: what is the measured fraction of negative queries?** A filter in front of a table that is usually hit is pure cost, and that fraction is a property of the customer's traffic, which means it belongs in the datasheet as an assumption.

X36. Cryptographic Engines, Sized

Crypto IP is one of the most commonly licensed categories, and it is unusual in that its correctness is binary, its specifications are published and testable, and its cost is dominated by a small number of arithmetic primitives. That combination makes it a good first product for a design house and a good subject for exact sizing.

X36.1 The three primitive families and their costs

Table 362. What each family needs from the hardware

Family	Examples	Core operation	Cost driver	Typical area
Block ciphers	AES, ChaCha, SM4	Substitution and permutation over a small state	The S-box, replicated	5–50 kGE
Hashes	SHA-2, SHA-3, BLAKE	A compression function over a message block	Adders and rotations; long carry chains in SHA-2	10–30 kGE
Public key	RSA, ECC, Diffie–Hellman	Modular exponentiation or point multiplication	The modular multiplier — dominates everything	50–500 kGE
Post-quantum	ML-KEM (Kyber), ML-DSA (Dilithium)	Polynomial arithmetic in a ring, NTT	NTT butterflies and modular reduction — Part X6's FFT with a different field	50–200 kGE
MAC / AEAD	GCM, Poly1305, CMAC	Carry-less or modular multiply-accumulate	$GF(2^{128})$ multiplier for GCM	10–40 kGE

Graduate · **Post-quantum cryptography is an opportunity for design houses precisely because it is new.** The standards are recent, the hardware literature is thin, the incumbent crypto-IP vendors' portfolios were built for RSA and ECC, and the core operation — the number-theoretic transform — is an FFT over a finite field, which means Part X6's entire architectural analysis transfers: the same radix choices, the same twiddle-ROM symmetries, the same memory-versus-multiplier trade. **A team that has built an FFT has most of what an NTT needs,** with the arithmetic replaced by modular arithmetic, and that is an unusually direct path from an existing competence to a new market.

X36.2 AES: where the area actually goes

The S-box is the block

	Step	Justification
1	AES-128 is ten rounds of SubBytes, ShiftRows, Mix-Columns, AddRoundKey.	<i>Specification.</i>
2	ShiftRows is wiring; AddRoundKey is 128 XORs; Mix-Columns is a fixed $GF(2^8)$ matrix — shifts and XORs.	All three are nearly free.
3	SubBytes applies a 256-entry nonlinear substitution to each of 16 bytes.	This is the whole cost.
4	As a table it is 16×2048 bits of ROM or $16 \times \sim 700$ gates synthesised.	<i>The naive implementation.</i>
5	Or compute it: the S-box is inversion in $GF(2^8)$ plus an affine map, and inversion decomposes through $GF((2^4)^2)$.	<i>Canright's tower-field construction reduces the S-box to roughly a third of the table's area, at the cost of more logic depth. The trade is area against frequency, and which side wins depends entirely on the throughput requirement.</i>
6	A round can use 16 S-boxes (one cycle per round), 4, or 1.	Throughput scales linearly with S-box count and so does area , which makes AES one of the cleanest area/throughput families to parameterise — and therefore a good product, because one design serves many customers.

Table 363. AES-128 area and throughput against S-box count, at 1 GHz

S-boxes	Cycles per block	bits/cycle	Gbit/s	Approx. gates	Mbit/s per kGE
16	10	12.8	12.8	13,200	969.7
8	20	6.4	6.4	7,600	842.1
4	40	3.2	3.2	4,800	666.7
1	160	0.8	0.8	2,700	296.3

Gate counts are indicative (700 GE per table-based S-box plus 2 kGE of state and key schedule). **The last column is nearly constant**, which is the signature of a cleanly scalable block: the customer chooses a point on the line rather than a different design.

Worked example 48. Which AES configuration does a 400 Gbit/s link need?

Given. MACsec on a 400 Gbit/s Ethernet port, AES-GCM, digital logic at 800 MHz.

Method. Work out bits per cycle, then how many parallel AES cores that implies, then check the GCM multiplier alongside it.

Line rate	400 Gbit/s
Clock	800 MHz
Bits per cycle required	500
AES block size	128
Blocks per cycle	3.906
Fully unrolled pipelined AES cores needed	4
Pipeline stages each (one per round)	10
$GF(2^{128})$ multiplies per cycle (GCM)	4
Dominant cost	the GCM multiplier, not AES

How this is got wrong. By sizing AES and forgetting the mode. Counter mode parallelises perfectly — each block's key-stream is independent — so AES scales by replication. The GCM authentication tag is a *sequential* multiply-accumulate in $GF(2^{128})$, which does not parallelise naively; making it keep up requires the standard trick of precomputing powers of the hash key and processing several blocks at once, which costs several 128-bit carry-less multipliers and their key storage. **At high line rates the authenticator is larger than the cipher**, and a datasheet that quotes only AES throughput has quoted the easy half.

X36.3 Public key: modular multiplication is the whole problem

Montgomery multiplication, and why division disappears

	Step	Justification
1	Modular multiplication needs $ab \bmod n$; the reduction is a division, which is expensive (Part X9).	<i>And it is needed thousands of times per operation.</i>
2	Montgomery's idea: work with $a\bar{\circ} = aR \bmod n$ for $R = 2^k > n$.	<i>A change of representation.</i>
3	Then $REDC(x) = (x + (xn' \bmod R)n)/R$ reduces using only multiplications and shifts , because dividing by R is a shift.	The division is gone. n' is precomputed once.
4	Conversion in and out costs two extra multiplications, amortised over the whole exponentiation.	<i>Negligible over thousands of operations.</i>
5	So an RSA engine is: a wide multiplier, an adder, a shifter, and a controller.	And the wide multiplier is 80–90 % of the area, <i>which is why the literature is about multiplier architectures and not about protocols.</i>

Table 364. Public-key work, measured in modular multiplications and cycles (64-bit multiplier, schoolbook, 500 MHz)

Operation	Modulus bits	Modular multiplies	64-bit words	Cycles (approx.)	Time (ms)
RSA-2048 (CRT)	1,024	3,072	16	196,608	0.3932
RSA-4096 (CRT)	2,048	6,144	32	1,572,864	3.146
ECC P-256	256	3,993	4	15,974	0.03195
ECC P-384	384	5,990	6	53,913	0.1078

Operation	Modulus bits	Modular multiplies	64-bit words	Cycles (approx.)	Time (ms)
X25519	255	3,315	4	13,260	0.02652

The multiplication counts are the standard estimates: square-and-multiply for RSA with the Chinese remainder theorem halving the modulus, and roughly a dozen field operations per elliptic-curve point addition. **The table explains the industry's migration:** ECC at 256 bits gives comparable security to RSA at 3072 and costs orders of magnitude less work.

A public-key engine that is merely correct is dangerous. The classical attacks are not on the mathematics but on the implementation: a square-and-multiply loop that branches on key bits leaks the key through timing and through power (Part X15), and a Montgomery ladder — which performs the same operations regardless of the bit — costs perhaps 30 % more work and removes the leak. Likewise a conditional subtraction at the end of a reduction is a data-dependent branch, so implementations make it unconditional. **Constant-time behaviour must be a stated requirement and a verified property**, not a side effect, and it is one of the few properties where a formal argument (no branch or memory access depends on secret data) is both achievable and genuinely convincing.

Problem. A customer wants a crypto accelerator supporting ‘all the usual algorithms’. How do you scope it?

Solution. Refuse the phrase and replace it with a table, because the algorithms differ in cost by two orders of magnitude and ‘all the usual’ hides that. Ask for, and write into the specification: **which algorithms and which parameter sets** — AES-128 and AES-256 differ only in rounds, but adding SHA-3 to a SHA-2 design is a completely separate datapath; **which modes**, since GCM costs more than the cipher at high rates; **what throughput for each**, separately, because a design sized for line-rate bulk encryption and one sized for occasional key exchange are different machines; **what attack model**, since side-channel countermeasures are a factor of two to four in area (Part X15) and are pointless if the part is in a locked rack; and **what certification**, because FIPS or Common Criteria brings its own known-answer tests, entropy requirements and documentation, and that cost exceeds the design cost. **The scoping conversation is the deliverable at this stage**, and a vendor who produces this table instead of a quote is demonstrating exactly the competence the customer is trying to buy.

X37. Bus Protocols: Ordering, Outstanding Transactions and Exclusives

Almost every block a design house sells attaches to an AMBA interface, and almost every integration problem is a protocol misunderstanding rather than a functional bug. The protocol's subtle points are few and they recur; this part works through them.

Five independent channels, each with its own handshake.

Independence is the source of both the throughput and the deadlocks.

Figure 47. The five AXI channels.

X37.1 The handshake, and the one rule that is always broken

VALID/READY, and why VALID may not wait

	Step	Justification
1	A transfer occurs on a rising edge when VALID and READY are both high.	<i>The basic handshake, shared by AXI, AXI-Stream, TileLink and CHI.</i>
2	Once VALID is asserted it must stay asserted until the transfer occurs , and the payload must not change.	<i>Otherwise the receiver cannot rely on what it sampled.</i>
3	VALID must not depend combinationaly on READY.	<i>This is the rule that is broken. If each side waits for the other, the two combinational paths form a loop and the interface deadlocks or oscillates — and a testbench with a permanently-ready receiver never exposes it.</i>
4	READY <i>may</i> depend combinationaly on VALID.	<i>The asymmetry is deliberate: it lets a receiver accept in the same cycle, which is where the throughput comes from.</i>
5	A registered-output, registered-ready skid buffer breaks any timing path across the interface at the cost of one cycle and two entries of storage.	<i>The standard remedy, and the right default for an IP boundary — Part X14's advice to register every boundary, in protocol form.</i>

The testbench that hides this bug is the default one. A driver that holds READY high permanently, or a monitor that never applies back-pressure, will never create the condition in which a combinational VALID-from-READY dependency matters. **Randomised back-pressure is not an optional refinement of an interface testbench; it is the only way the interface is tested at all.** The same applies to the master side: a stimulus that never delays VALID does not test the slave's ability to wait. Both are one line of constrained randomisation and both routinely go missing.

Table 365. Interface buffering options and what each costs

Structure	Added latency (cycles)	Throughput (transfers/cycle)	Timing path across the boundary	Full rate?
Combinational pass-through	0	1	none	yes
Register slice, forward only	1	1	broken	yes
Register slice, both directions (skid)	1	1	broken	yes
Naive register on both, no skid	1	0.5	broken	halved
Two-deep FIFO	2	1	broken	yes

The fourth row is the trap: registering both VALID and READY without a skid buffer halves the throughput, because the master cannot present a new value until it has seen the registered READY. It looks correct in a functional test and shows up as a performance shortfall at integration.

X37.2 Ordering: what the protocol guarantees and what it does not

Table 366. AXI ordering rules, and the integration failures each one causes

Rule	What it means	The bug it causes when forgotten
Same ID, same direction → ordered	Responses come back in order for one ID	A slave that reorders within an ID breaks masters that rely on it

Rule	What it means	The bug it causes when forgotten
Different IDs → no order guarantee	Responses may interleave arbitrarily	A master that assumes order across IDs corrupts data
Reads and writes are not ordered relative to each other	A read issued after a write may complete first	Read-after-write hazards in a customer's driver ; needs an explicit barrier or a completion wait
Write response means accepted, not visible	B arrives when the slave takes responsibility	Assuming data is observable by another master — it may not be
Bursts must not cross 4 kB boundaries	A page-crossing burst is illegal	A DMA that ignores it produces a protocol violation the interconnect may not check
Narrow transfers use strobes	WSTRB selects lanes	A slave ignoringWSTRB corrupts neighbouring bytes

Worked example 49. How many IDs does a master need?

Given. A DMA engine with 8 GB/s of read bandwidth, a 400 ns round trip, 512-byte bursts, on a 256-bit interface at 1 GHz.

Method. Bandwidth–delay product decides outstanding bursts; whether they need distinct IDs depends on whether the engine can accept out-of-order data.

Bytes in flight needed	3.125 kB
Outstanding bursts	7
If all use one ID	responses are ordered — simple, but one slow slave blocks everything behind it
If each uses a distinct ID	reordering allowed — needs a reorder buffer
Reorder buffer size	3.125 kB
ID bits needed	3
Recommended	a few IDs, grouped by destination

How this is got wrong. By choosing one extreme. A single ID gives head-of-line blocking: a request to slow memory stalls every completed request behind it, and the measured bandwidth collapses when the traffic is mixed. Distinct IDs everywhere give full reordering freedom and cost a reorder buffer of the full bandwidth–delay product plus the logic to fill it. **The usual answer is a small number of IDs partitioned by destination** — one per memory region or per outstanding stream — which removes head-of-line blocking between unrelated traffic while keeping ordering, and therefore simplicity, within a stream.

X37.3 Exclusive access, and why it is harder than it looks

Load-linked / store-conditional in bus form

	Step	Justification
1	An exclusive read records a monitor for that address and master.	AXI's ARLOCK exclusive, or the processor's load-linked.
2	An exclusive write succeeds only if the monitor is still set.	It returns EXOKAY on success and OKAY on failure — and OKAY means the write did not happen , which software must check.
3	Any intervening write to the address by anyone clears the monitor.	That is what makes it atomic.
4	The monitor is in the slave or the interconnect, not the master.	So an IP block containing memory that must support exclusives has to implement the monitor — and the number of simultaneous monitors it supports is a specification item that is routinely omitted.
5	Monitors may be granted at a granularity coarser than one address.	Which causes false failures: two masters using different addresses in the same granule livelock each other. The granule size must be documented.
6	Spurious failure is always permitted, so software must loop.	Hardware is allowed to be conservative; software must not assume success. A driver that does not loop works on one implementation and hangs on another.

Graduate · **Atomics moved from the master to the interconnect, and an IP vendor should know which era their customer is in.** The load-linked / store-conditional model requires a monitor per master and a retry loop, and it scales badly with core count because contention causes repeated failures. Newer AMBA revisions add *far atomics*: the master sends the operation (add, swap, compare and swap) to the point of coherence and receives the result, so the round trip happens once regardless of contention. **For a block containing shared state, supporting far atomics can be far cheaper than supporting exclusives** — an ALU beside the memory rather than a monitor table — and it performs better under contention. Asking the customer which their system uses is a scoping question worth raising early.

Problem. Your block's register interface is APB and the customer complains of poor configuration throughput. What do you say?

Solution. That APB is doing exactly what it is for, and then offer the two real options. APB is deliberately simple — no pipelining, no outstanding transactions, two cycles per access minimum — because a configuration bus should be trivial to implement and verify, and configuration is not a throughput problem. If the customer is writing thousands of registers at boot and it matters, the causes are usually not the bus: a slow bridge clock ratio, a synchroniser per access, or software doing read-modify-write where a write would do. **Measure before changing the interface.** If it genuinely is the bus, the options are to **add a small DMA or descriptor engine** that replays a register image from memory — which is what blocks with large coefficient tables do, and it moves the traffic to AXI where it belongs — or to **provide an AXI-Lite alternative** for the register file. **Adding coefficient memory behind a streaming interface, rather than behind the register bus, is the structural fix**, and it is worth designing in from the start for any block whose configuration is more than a few hundred words.

X38. Colour, the ISP Pipeline and Display Processing

Camera and display IP is one of the largest licensing markets, and it is unusual in that the correctness criterion is partly perceptual. That does not make it unquantifiable — it makes the quantities colorimetric rather than signal-theoretic, and they are just as computable.

Demosaic is the boundary: before it one value per pixel, after it three.

Everything upstream is a third of the data rate — and that is where the fixes belong.

Figure 48. A minimal image signal processor. The order is not arbitrary: each stage assumes the previous ones have run.

X38.1 Why the pipeline is in that order

Table 367. Each stage, what it corrects, and why it must come where it does

Stage	Corrects	Why here
Black level	Sensor pedestal and dark current	First — everything downstream assumes zero means zero
Defect pixel	Stuck sensor pixels	Before demosaic, or the defect spreads to neighbours
Lens shading	Vignetting, colour shading	Before white balance, because the shading is colour dependent
Demosaic	One colour per pixel → three	The data rate triples here; everything possible is done before it
White balance	Illuminant colour	Per-channel gains; conventionally applied on the Bayer data for cost
Colour correction matrix	Sensor spectral response → a standard space	Needs three channels, so after demosaic
Gamma / tone	Perceptual coding	After all linear operations — averaging gamma-encoded values is wrong, and doing it is the commonest ISP bug
Sharpen, noise reduction	Perceptual quality	After tone mapping, because the visibility of noise is nonlinear

Gamma is the ordering rule that is broken most often, and the error is visible. Gamma encoding is a nonlinear map applied so that the limited code space is distributed according to human contrast sensitivity. Linear operations — scaling, blending, resizing, demosaicing, averaging — are only correct on *linear* light. Resizing a gamma-encoded image darkens edges and shifts colours; alpha-blending gamma-encoded values produces halos. **The fix is to keep the pipeline linear until the final encode**, and where hardware must operate on encoded data, to linearise and re-encode around the operation. This is a real and recurring defect in shipped display and camera pipelines, and it is worth an explicit statement in an IP block's datasheet about which domain its input and output are in.

Table 368. Measured error from averaging in the gamma domain ($\gamma = 2.2$), linear light values

Value A	Value B	Correct average (linear)	Average of encoded values, decoded	Error (%)
0	1	0.5	0.2176	-56.47
0.2	0.8	0.5	0.4454	-10.93
0.4	0.6	0.5	0.4945	-1.102
0	0.5	0.25	0.1088	-56.47
0.5	1	0.75	0.7266	-3.121

Computed directly. **The first row is the worst case and it is a 26 % error** — averaging black and white in the encoded domain gives a result noticeably darker than mid-grey. This is why image scaling in the wrong domain looks wrong rather than merely inaccurate.

X38.2 Colour spaces as matrices

Why colour conversion is a 3×3 matrix and when it is not

	Step	Justification
1	Human colour vision has three cone types, so colour is a three-dimensional quantity.	<i>Trichromacy. Two spectra that produce the same cone responses look identical — metamerism.</i>
2	A display's primaries span a triangle in chromaticity space; its gamut is that triangle.	<i>Any colour inside is reproducible; outside is not.</i>
3	Converting between two sets of primaries is a change of basis: a 3×3 matrix on linear tristimulus values.	Linear is load-bearing — see X38.1.
4	So BT.709 to BT.2020, or camera RGB to XYZ, is one matrix multiply per pixel.	<i>Nine multiplies and six adds — trivial hardware, which is why colour conversion is never the bottle-neck.</i>
5	It stops being a matrix when the gamut does not contain the colour, or when the transfer function is not a power law.	Gamut mapping is a nonlinear, perceptual and proprietary operation , and HDR transfer functions (PQ, HLG) are not power laws, so they need a LUT. Those two are where display IP actually differentiates.

Table 369. Gamut areas in CIE xy, computed from the primaries

Space	Red (x,y)	Green (x,y)	Blue (x,y)	Triangle area	Relative to BT.709 (%)
BT.709 / sRGB	0.64, 0.33	0.3, 0.6	0.15, 0.06	0.112	70.83
DCI-P3	0.68, 0.32	0.265, 0.69	0.15, 0.06	0.152	96.08
BT.2020	0.708, 0.292	0.17, 0.797	0.131, 0.046	0.2119	133.9
Adobe RGB	0.64, 0.33	0.21, 0.71	0.15, 0.06	0.1512	95.54

Areas computed as the triangle area of the primaries in the xy chromaticity diagram. **xy area is a crude perceptual measure** — the diagram is not perceptually uniform, so these percentages overstate the green region and understate the blue — and it is the number most commonly quoted, which is worth knowing when reading a display specification.

X38.3 Line buffers: the memory that sets ISP area

Worked example 50. Why an ISP is mostly SRAM

Given. A 4K (3840-wide) pipeline, 12 bits per channel. The stages need vertical neighbourhoods: demosaic 5 lines, noise reduction 7, sharpening 5, lens shading 1, scaler 4.

Method. Each stage that looks at neighbouring rows must buffer those rows, because the sensor delivers one row at a time. Count the lines and the bits.

Line width	3,840
Bits per pixel (Bayer, pre-demosaic)	12
Demosaic: 5 lines	28.12 kB
Noise reduction: 7 lines (RGB, 36 bit)	118.1 kB
Sharpen: 5 lines (RGB)	84.38 kB
Scaler: 4 lines (RGB)	67.5 kB
Total line buffers	298.1 kB
As a fraction of a typical ISP's area	the majority

How this is got wrong. By counting arithmetic and not lines. The filters are small — a 5×5 convolution is 25 multiplies — and the line buffers are hundreds of kilobytes. Two consequences follow and both are architectural. **Process in tiles or stripes** rather than full lines where the algorithm permits, trading a small overlap region for a large memory saving; this is why many ISPs are tile-based. And **fuse stages** so one buffer serves several neighbourhoods rather than each stage buffering separately — the same fusion argument as in Part X13's accelerator dataflow, arriving in a completely different domain.

Table 370. Line-buffer memory against tile width (8-pixel halo)

Image width	Tile width	Line buffer (kB)	Overlap overhead (%)	Memory vs. full line (%)
1,920	full line	149.06	0	100
1,920	256	19.875	3.12	13.33
1,920	512	39.75	1.56	26.67
3,840	full line	298.12	0	100
3,840	256	19.875	3.12	6.667
3,840	512	39.75	1.56	13.33
7,680	full line	596.25	0	100
7,680	256	19.875	3.12	3.333
7,680	512	39.75	1.56	6.667

Tiling trades a few per cent of redundant computation for an order of magnitude of memory, and the trade improves as resolution rises, which is why 8K pipelines are tiled and 1080p ones often are not.

Problem. A customer says your ISP's output does not match their reference software. Where do you look?

Solution. Almost always at a convention rather than at the arithmetic, and the candidates are few enough to enumerate. **Domain:** is the reference operating on linear or encoded values at the stage that differs? X38.1's error is large and looks like a gain error. **Rounding and clipping:** a pipeline that clips intermediate values to the output range destroys headroom that the reference keeps, and the difference appears only in highlights. **Chroma siting and subsampling phase:** 4:2:0 has several legal sitings and choosing the wrong one produces a half-pixel colour shift that is invisible on most content and obvious on a colour edge. **Matrix coefficients and range:** limited versus full range, and BT.601 versus BT.709 coefficients, are four combinations and three of them are wrong. **Demosaic algorithm,** which is genuinely allowed to differ and is where a vendor's quality claim lives. **Establish which by bypassing stages one at a time** — which requires the block to have bypass controls, and that is a design decision worth making early for exactly this conversation.

X39. Clock Generation, Distribution and Time Synchronisation

Clocking is the one subsystem every block depends on and few specifications describe adequately. This part covers the three parts an IP designer must be able to reason about: how the clock is made, how it is delivered, and how time is agreed between chips.

X39.1 Spread spectrum: trading a specification for a specification

Why modulating the clock reduces measured emissions

	Step	Justification
1	Radiated emission is measured in a receiver with a defined resolution bandwidth — 120 kHz for CISPR above 30 MHz.	<i>The regulation specifies the measurement, not the physics.</i>
2	An unmodulated clock puts all its harmonic energy in one line, far narrower than that bandwidth.	<i>So the receiver sees the whole harmonic.</i>
3	Modulating the frequency by $\pm 0.5\%$ spreads each harmonic over $\pm 0.5\%$ of its frequency.	<i>The nth harmonic spreads n times as far, so higher harmonics benefit more.</i>
4	The receiver now sees only the fraction of the energy inside its bandwidth , so the reading falls by roughly $10 \log_{10}(\text{spread/RBW})$ dB.	<i>The total radiated energy is unchanged. The compliance number improves; the physics does not.</i>
5	Cost: the clock period now varies, so every synchronous budget must hold at the fastest excursion, and any PLL downstream must track the modulation.	<i>Which is why a SerDes reference clock's spread must be negotiated — the CDR's loop bandwidth must exceed the modulation rate or it cannot follow.</i>

Table 371. Spread-spectrum reduction in a 120 kHz measurement bandwidth

Clock (MHz)	Spread ($\pm\%$)	Harmonic	Spread width (MHz)	Reading reduced by (dB)
100	0.5	1	1	9.208
100	0.5	5	5	16.2
100	0.5	10	10	19.21
100	1	1	2	12.22
100	1	5	10	19.21
100	1	10	20	22.22
1000	0.5	1	10	19.21
1000	0.5	5	50	26.2
1000	0.5	10	100	29.21
1000	1	1	20	22.22
1000	1	5	100	29.21
1000	1	10	200	32.22
5000	0.5	1	50	26.2
5000	0.5	5	250	33.19
5000	0.5	10	500	36.2

Computed from the ratio of spread width to resolution bandwidth. **The fundamental barely benefits and the tenth harmonic benefits a lot**, which matches measured practice and is why spread spectrum is judged on the harmonics that actually fail the mask.

Spread spectrum and a synchronous interface are frequently incompatible, and the incompatibility is found late. Any interface whose two ends derive their clocks from different sources must absorb the frequency difference; spreading one side makes that difference time-varying at the modulation rate, typically 30–33 kHz. An elastic buffer sized for a static 200 ppm offset (Part Y3) will underflow or overflow when the offset swings by ± 5000 ppm at 33 kHz. **The remedies are to spread both ends from the same source, to size the elastic buffer for the modulation, or to forbid spreading on that interface** — and which one applies is a system decision that must be recorded in the IP's integration guide, because the block cannot detect the problem.

X39.2 The clock tree, and what it costs

Table 372. Clock tree cost at 1 GHz, 0.8 V (indicative 5 fF per flop clock pin, fanout 4)

Flops	Buffer levels	Buffers	Total clock capacitance (pF)	Clock power (W)	Insertion delay (ps)
10,000	7	3,333	60	0.0384	210
100,000	9	33,333	600	0.384	270
1,000,000	10	333,333	6000	3.84	300
10,000,000	12	3,333,333	60000	38.4	360

***Indicative constants.** The shape is what matters: clock power is a large fraction of total dynamic power (Part X7 measured two thirds on a small block), and insertion delay grows logarithmically — which is harmless for setup and hold, since only skew matters (Part X2), and very harmful for anything that compares clock phase across a boundary.*

Table 373. Clock distribution styles

Style	Skew	Power	Where
Balanced H-tree	Low by construction	High — long wires	Top-level distribution in large chips
Buffered tree from CTS	Tool-balanced, a few tens of ps	Moderate	The default for a block
Mesh / grid	Very low	Highest — the whole grid switches	High-performance processors
Clock gating (integrated cell)	Adds a level	Saves 20–40 %	Everywhere — Part X7
Resonant / rotary	Low	Potentially much lower	Research and a few products; needs inductors

Undergraduate review · **Why a block should provide one clock input and do its own gating, rather than accepting several clocks.** Every additional clock at an IP boundary is a domain crossing the integrator must analyse, constrain and verify, and the constraints must be written by someone who understands both sides — which at integration time is nobody. A block that takes one clock and derives its internal enables is far easier to integrate, and the power saving from gating is identical. **Where a second clock is genuinely required** — a slower configuration domain, a recovered receive clock — **the crossing belongs inside the block, documented, with its constraints shipped.** That is a concrete piece of value a vendor adds, and its absence is a concrete integration cost.

X39.3 Agreeing on time: IEEE 1588 and the hardware it needs

Why timestamping must be in the PHY

	Step	Justification
1	Two nodes exchange timestamped messages; the offset is $((t_2 - t_1) - (t_4 - t_3))/2$.	<i>The standard two-way exchange.</i>
2	This assumes the path is symmetric .	Any asymmetry appears directly as half of it in the offset — an error no amount of averaging removes.
3	Every variable delay between the timestamp point and the wire is asymmetry.	<i>Software stacks, driver queues, interconnect arbitration, and even FIFO occupancy in the MAC.</i>
4	So the timestamp must be taken as close to the wire as possible , in hardware, at a defined reference plane.	<i>Typically the start-of-frame delimiter crossing the MII interface, which is why PTP support is a PHY and MAC feature rather than a software one.</i>
5	Residual asymmetry (different cable lengths, different PHY latencies for TX and RX) must be <i>calibrated</i> and subtracted.	Which means the block must expose a program-mable correction , and a datasheet must state the TX and RX latency and its variation — a number customers doing PTP will ask for and many data-sheets omit.

Table 374. Where the timestamp is taken decides the achievable accuracy

Timestamp point	Delay variation (ns)	Offset error contribution (ns)	Equivalent distance error (m)
Software timestamp	1.0000×10^5	50000	15000
Driver, kernel	10000	5000	1500
MAC, hardware	100	50	15
MII reference plane	8	4	1.2
PHY, sub-ns aware	1	0.5	0.15

Indicative figures for each point in the stack. **The jump from software to hardware timestamping is three orders of magnitude**, which is why sub-microsecond synchronisation is a hardware feature and not a protocol choice.

Problem. Your block must generate a clock that is frequency-locked to a recovered network clock. What are the options?

Solution. Three, and they differ in what they require from the system rather than in accuracy. **An analogue PLL locked to the recovered clock** is the classic answer: lowest jitter, and it needs an analogue block and a recovered clock brought out as a real clock signal, which constrains the floorplan and the package. **A digitally controlled oscillator driven by a digital PLL** — measure the phase error in digital logic, filter it, and steer a fractional-N synthesiser — keeps the loop in synthesisable logic, is portable between processes, and has more jitter; it is what most modern implementations do, and the loop design is Part X21's arithmetic. **Or adjust time rather than frequency:** run the local clock free and maintain a software-visible time base that is rate-corrected, which needs no clock hardware at all and is sufficient whenever the requirement is on *timestamps* rather than on a physical output clock. **The third is far cheaper and is frequently the right answer**, so the scoping question is whether the customer needs a synchronised clock pin or synchronised time, and those are very different products.

X40. The Coverage Map: Which Theory an IP Block Uses

This book covers the theory that is used when designing, modelling and verifying semiconductor IP, and deliberately does not cover theory that is not. This part is the map: **51 topic areas**, what each one is used for in a real block, and where it is treated here. It is meant to be read as a checklist — if you are asked about a block and cannot find its theory in this table, the table has a gap and the gap is worth reporting.

Table 375. Theory used in IP design, and where this book treats it

Topic	Where it is used in a real block	Chapters
Signals and systems, LTI, convolution	Every filter, equaliser, channel model	A1, E1, X22
Fourier, Laplace, z-transform, poles and zeros	Filter design, loop stability, spectral analysis	A2, X23
Sampling, aliasing, reconstruction	Every converter boundary; rate change	A3, X22, X12
Probability, random processes, noise	Link budgets, yield, jitter, metastability	A4, X25, X16, X3
Detection and estimation, likelihood, CRB	Receivers, synchronisation, calibration loops	X25
Information theory, capacity, entropy	Code choice, compression, quantiser design	I1, X25, X29
Linear algebra, SVD, conditioning	MIMO, beamforming, calibration, word lengths	A5, X24, X30
Numerical methods, iteration, refinement	Dividers, square root, matrix engines	X9, X24
Optimisation: convex, ILP, graph algorithms	Every EDA tool; word-length allocation; scheduling	I3, X26
Boolean algebra, BDD, SAT	Equivalence checking, formal, ATPG	Z2, X33
Automata and FSM theory	Control logic, protocol checkers, parsers	Z3, C2
Graph theory	STA, retiming, clock skew scheduling, routing	I4, X26, X34
Finite fields and modular arithmetic	Reed-Solomon, BCH, AES, GCM, RSA, ECC	I2, X5, X36
Number theory	Public-key engines, NTT for post-quantum	R1, X36
Coding theory: block, convolutional, LDPC, polar	Every link and every storage device	F2, X5, X29
Cryptographic primitives and side channels	Security IP, roots of trust, secure boot	H3, X15, X36
Fixed-point arithmetic, quantisation, dither	Every DSP block without exception	X1
Computer arithmetic: adders, multipliers, division, CORDIC	Every datapath	C1, X9
Floating point and mixed precision	DSP, ML accelerators, scientific blocks	X9, X13
Semiconductor device physics	Delay, leakage, variability, reliability	L1, B1, X16
CMOS circuits, logical effort, sizing	Every gate; the sizing the tool performs	B2, X26, X34
Timing: setup, hold, skew, corners, OCV	Sign-off of every block	B3, X2
Metastability and clock domain crossing	Every multi-clock design	C3, X3
Interconnect RC, crosstalk, transmission lines	Long wires, I/O, package, board	B4, X14, G1
Power: dynamic, leakage, DVFS, gating	Every block's specification	B2, X7
Power delivery network, IR drop, di/dt	Any block with large switching current	X32

Topic	Where it is used in a real block	Chapters
Thermal	Packaging limits, throttling, reliability	L3, X16
Analogue blocks: kT/C, matching, gain-bandwidth	Converters, PHYs, PLLs, sensor interfaces	B5, X31
Data converters and time interleaving	Every mixed-signal boundary; SerDes DSP receivers	X12, X31
PLL, CDR, jitter and phase noise	Every clock and every link	X12, X21, X39
Feedback and control in digital loops	Adaptation, AGC, calibration, thermal	L4, X21
Memory: SRAM, DRAM, ECC, multi-port	The largest object in most blocks	J1, X10
Caches and coherence	Processor and accelerator subsystems	D3, X28
Computer architecture: ISA, pipelines, hazards	Processor IP; any block behind one	D1, D2, X19
Interconnect protocols and ordering	Every block's boundary	J3, X11, X37
Queueing and performance modelling	Buffer sizing, QoS, latency budgets	Q1, X18
Hardware data structures: CAM, hashing, Bloom	Networking, storage, security IP	X35
Compression and entropy coding	Codecs, storage, trace	J4, X20
Image and colour science	Camera and display IP	M3, X38
Wireless PHY: OFDM, MIMO, synchronisation	Modem IP	K1, X30
Wireline PHY: equalisation, PAM, FEC	SerDes, Ethernet, PCIe	F1, X4, Y2, Y3
Electromagnetics and antennas	RF front ends, package, EMC	G1, Q4
Radar and sensing signal processing	Automotive and industrial IP	G2
Machine learning and quantisation	NPU IP and any block that embeds one	M2, X13
Logic synthesis, mapping, retiming	The flow every block passes through	X34
Physical design, congestion, floorplanning	What your RTL makes easy or impossible	N2, X14
Design for test: scan, ATPG, BIST, compression	Every chip that is manufactured	R2, X27
Reliability, yield, statistics, functional safety	Pricing, qualification, automotive markets	K3, N3, X16
Verification theory: coverage, mutation, formal	Half the effort of every block	H1, X8, X33
High-level synthesis internals	Exploration; some production blocks	Q2, Y12
Hardware-software interface, registers, drivers	Every block with a control plane	M1, Y10

X40.1 What is deliberately left out, and why

Excluding material is a decision that should be stated rather than left as an omission a reader discovers. The following areas are part of a broad electrical-engineering or computer-science education and are not part of the daily work of an IP design house, so they are absent or covered only for context.

Table 376. Out of scope, with the reason

Area	Why it is not here
Compiler theory beyond HLS scheduling	A block does not compile; the tool does
Operating system internals	Relevant to the driver author, not to the RTL
Distributed consensus	A chip is not a distributed system in that sense

Area	Why it is not here
Computability and complexity as such	Except where it classifies an EDA problem — that part is in X26
Quantum computing	Included briefly for context only; no current IP block uses it
Database theory, web systems, graphics rendering pipelines	Different industries

The boundary is a judgement and it moves. Two of the rows above were inside the boundary twenty years ago and are outside it now, and at least one — machine learning — moved the other way within a decade. The test applied here is concrete: **does a working IP engineer use this to make a decision about a block?** If a topic only ever appears as background for a decision someone else makes, it is context rather than content, and this book says so instead of padding.

Problem. You are handed a block type this map does not cover. How do you find its theory?

Solution. Work backwards from the three questions every block must answer, because each one names a body of theory. **What does it compute, and how accurately?** That is the algorithm and its numerical behaviour — a signal-processing, coding or arithmetic question, and Parts X1 and X24 give the tools for the accuracy half whatever the algorithm is. **How fast must it go, and what does that cost?** That is Part X2's timing budget and Part X18's queueing, and the answer is always a parallelism and memory-bandwidth analysis — Part X13's roofline applies far outside machine learning. **How will you know it is right?** That is Part X8, and it is domain independent. **Only the first question has domain-specific theory**, and for that the fastest route is the standard's own reference implementation plus one survey paper, read in the order Part Y6 prescribes. The structure of the investigation does not change with the domain, which is the most portable thing this book has to offer.

X41. DRAM: The Timing That Shapes Every Memory Controller

Off-chip memory is where most systems spend most of their latency and a large part of their power, and its behaviour is not a simple latency number. A DRAM device is a state machine with a dozen timing constraints, and whether your block gets the bandwidth it was promised depends almost entirely on its access pattern rather than on the interface's rated speed.

X41.1 The bank, the row and the reason access order matters

Why a DRAM read is three operations, not one

	Step	Justification
1	A DRAM array stores each bit as charge on a capacitor, read by dumping it onto a bit line.	The read is destructive — the charge is consumed.
2	ACTIVATE opens a row: the whole row is sensed into the sense amplifiers, which form the <i>row buffer</i> .	Thousands of bits at once. This takes t_{RCD} .
3	READ or WRITE then accesses columns within the open row.	Fast — the data is already in the sense amplifiers. A second access to the same row is far cheaper than the first.
4	PRECHARGE writes the row back and restores the bit lines.	Takes t_{RP} . Required before opening a different row in the same bank.
5	So three cases: row hit, row miss (different row, same bank), and bank hit with a different bank.	Their costs differ by a factor of three or more, which is why access ordering is the memory controller's main job.
6	And the whole array must be refreshed periodically, because the charge leaks.	Refresh steals bandwidth and blocks access to a bank while it runs.

Table 377. Read latency by case, DDR4-3200 (indicative $t_{CL}=t_{RCD}=t_{RP}=22$)

Case	Cycles	Latency (ns)	Relative to a row hit
Row hit (open row)	22	13.75	1
Row miss, same bank	66	41.25	3
Different bank, row hit	22	13.75	1
Different bank, row miss	44	27.5	2

Indicative JEDEC-speed-bin numbers, not a datasheet. The ratio is the point: the same DRAM delivers data in 14 ns or 41 ns depending entirely on which row was previously open.

Table 378. Measured row-buffer hit rate and the bandwidth it implies, 16 banks, 20 000 accesses

Access pattern	Row hit rate	Row miss rate	Total time (μ s)	Bandwidth as % of the row-hit-only case
Sequential	0.8748	0.1252	343.86	79.97
Stride 4 kB	0.5	0.5	550	50
Random	0	1	825	33.33
Two interleaved streams	0	1	825	33.33

Simulated with a simple address decode (bank bits low, row bits high). **The same device delivers between a third and all of its rated bandwidth, decided by the access pattern alone. This is why a block's DMA pattern is a system-level specification item.**

X41.2 What the memory controller does about it

Table 379. Controller techniques and what each attacks

Technique	Attacks	Cost
Address mapping	Which bits select bank, row and column	Free, and it decides everything — interleaving banks on low bits turns a sequential stream into parallel bank accesses
Bank interleaving	Row-miss latency	Needs enough banks and enough outstanding requests
Request reordering (FR-FCFS)	Serves row hits before older row misses	A scheduling queue; and it makes latency unfair between requesters
Write batching	Bus turnaround, which costs several cycles	Write buffer; adds read latency when it drains
Open-page vs closed-page policy	Whether to leave a row open	Open wins on locality, closed wins on random traffic — a workload decision
Refresh scheduling	Refresh blocking a bank	Per-bank refresh and postponement; the device sets the limits

FR-FCFS scheduling makes DRAM latency unfair, and that unfairness reaches your block. A scheduler that prioritises row hits gives enormous throughput to a requester with good locality and can starve one with poor locality almost indefinitely — a real-time display fetch behind a streaming accelerator is the classic case. Systems therefore add per-requester quotas or deadline awareness, which is Part X11's arbitration argument arriving at the memory controller. **For an IP vendor the consequence is concrete:** a latency figure measured in isolation is not the latency your block will see, and any real-time guarantee must be expressed as a requirement on the system's memory scheduler, not assumed.

Table 380. Peak bandwidth of common memory interfaces

Interface	MT/s	Bits per channel	Channels	Peak GB/s	Relative to one DDR4-3200 channel
DDR4-3200	3200	64	2	51.2	2
DDR5-6400	6400	64	2	102.4	4
LPDDR5-6400	6400	32	4	102.4	4
HBM2E	3200	1,024	1	409.6	16
HBM3	6400	1,024	1	819.2	32

Peak, which nothing achieves. **HBM's advantage is width, not speed** — a thousand-bit interface at a modest rate, possible only because it is stacked on an interposer rather than routed on a board, which is why it costs what it does.

X41.3 Refresh, and why it gets worse

Worked example 51. What refresh costs at each density

Given. DDR4 requires all rows refreshed every 64 ms (32 ms above 85 °C). Refresh is issued as 8192 commands per interval, each occupying the device for t_{RFC} .

Method. Compute the fraction of time spent refreshing at several densities, where t_{RFC} grows with density because more rows are refreshed per command.

Refresh interval	64 ms
Commands per interval	8,192
t_{RFC} at 8 Gbit	350 ns
Time refreshing	4.48 %
t_{RFC} at 16 Gbit	550 ns
Time refreshing	7.04 %
At 32 Gbit and 95 °C (32 ms interval)	22.53 %
Trend	refresh overhead grows with density and with temperature

How this is got wrong. By assuming refresh is a rounding error. It was, at low density and room temperature; at high density in a hot enclosure it approaches a quarter of the device's time, and during a refresh the affected bank is unavailable, so the *latency tail* grows faster than the average. **Any block with a hard real-time deadline on a DRAM access must budget for a refresh collision**, and the number to budget is t_{RFC} at the maximum operating temperature, which a datasheet should state and a system integrator should be asked for.

Problem. Your accelerator needs 40 GB/s and the system has one DDR5 channel rated at 51 GB/s. Is that enough?

Solution. Almost certainly not, and the calculation to show it is short. Start from the rated figure and subtract, in order: **refresh**, a few per cent to a quarter depending on density and temperature; **read/write turnaround**, several cycles each time the bus direction changes, which for a mixed read-write stream costs 10–20 %; **row misses**, from the measurement in X41.1, which for anything but a sequential pattern is the largest term; and **other requesters**, because the channel is not yours. A realistic efficiency for a well-behaved streaming pattern sharing a channel is 60–75 %, giving 30–38 GB/s — below the requirement. **The productive response is not to ask for a faster channel but to reduce the demand:** tile the computation so data is reused on chip (Part X13), compress the traffic (Part X20's reference compression), or restructure the access pattern for row locality, which the measurement above shows can be worth a factor of two on its own. **And whatever is decided, the efficiency assumption belongs in the datasheet**, because the customer will measure it.

X42. Reset, Initialisation and the States Nobody Simulates

Reset is the least interesting part of a design and the source of a disproportionate share of silicon bugs, for a simple reason: simulation starts from a clean state and silicon does not. This part treats reset with the same seriousness as the datapath, because the failures it causes are the ones that appear only in the lab.

X42.1 Synchronous, asynchronous, and the one that is actually used

Table 381. Reset styles

Style	Assertion	De-assertion	Cost	Problem
Synchronous	On a clock edge	On a clock edge	Wider reset net timing; needs a running clock	Cannot reset a block whose clock has not started
Asynchronous	Immediate	Immediate	Cheap — the flop's async pin	De-assertion can violate recovery/removal and cause metastability
Asynchronous assert, synchronous de-assert	Immediate	Synchronised to the clock	A two-flop synchroniser per domain	None — this is the standard answer
No reset (initialised by first write)	—	—	Free — saves the reset net on datapath flops	X-propagation until written; needs care in verification

Why de-assertion is the dangerous edge

	Step	Justification
1	A flop with an asynchronous reset has <i>recovery</i> and <i>removal</i> times: the reset must be stable for a window around the clock edge.	<i>Exactly analogous to setup and hold, and checked by the same static timing analysis.</i>
2	Reset assertion is asynchronous and harmless: the flop goes to its reset value whenever it arrives.	<i>There is no race, because the destination is unconditional.</i>
3	De-assertion races the clock.	<i>If reset releases within the recovery window, the flop may go metastable or may capture the pre-reset value.</i>
4	With one clock, the tool checks and fixes it.	<i>Recovery and removal are ordinary timing checks.</i>
5	With a large design, the reset tree's own skew means different flops leave reset on different cycles.	<i>A state machine can then advance while part of its state is still reset, reaching a state the designer never enumerated. This is the classic reset bug and it is invisible in RTL simulation, where reset de-asserts everywhere at once.</i>
6	Remedy: synchronise the de-assertion in each clock domain, and treat the reset tree like a clock tree.	Balanced, buffered, and timed.

Reset de-assertion skew produces states that no simulation visits, and gate-level simulation with timing is the only place it appears before silicon. In RTL simulation the reset signal changes at one instant for every flop. In silicon it is a buffered tree with tens or hundreds of picoseconds of skew — more if it is not treated as a timed net — so flops leave reset on different clock edges. A counter can start counting while its comparator is still held; a FIFO's write pointer can advance while its read pointer is reset, making the FIFO appear full at power-up. **The two defences are structural:** synchronise de-assertion

per domain so all flops in a domain release on the same edge, and design state machines so that a partially-reset state is not reachable — usually by holding the whole machine in an idle state until an explicit enable.

X42.2 X-propagation: where simulation lies in both directions

Table 382. How simulators treat unknown values, and why it matters

Situation	RTL simulation	Silicon	Consequence
Uninitialised flop read	X	A definite 0 or 1, randomly	Simulation may be more pessimistic than reality
if (x) where x is X	Takes the else branch	Takes one branch definitely	X-optimism: the bug is hidden
case with X selector	May take the default	Takes a real branch	Same optimism
Mux with X select	Output X if inputs differ; output the value if they are equal	Real value	Can hide or expose
Flop with X data	Captures X	Captures a real value	X-pessimism: X spreads where silicon would not

Graduate · **X-optimism and X-pessimism are both wrong, in opposite directions, and the remedies differ.** Optimism hides bugs: a branch on an unknown silently resolves, so a design that depends on an uninitialised value appears to work in simulation and behaves randomly in silicon. Pessimism wastes time: X floods through a design that silicon would run correctly, and engineers add resets they do not need to make simulation quiet — which costs area and reset-tree power on every flop. **The industrial answers are three:** X-propagation-aware simulation modes that make branches on X produce X rather than choosing; **random initialisation**, where every uninitialised flop starts at a random value and the regression is run with many seeds, which converts X-optimism into an ordinary functional failure the testbench can catch; and gate-level simulation, which has no X-optimism because the gates are real. **Random initialisation is the cheapest and the most effective,** and it is available in every simulator.

Table 383. Probability of catching a dependence on one uninitialised bit, with random initialisation

Unreset flops	Random seeds run	P(at least one seed exposes it)	P(missed) (%)
100	1	0.5	50
100	10	0.999023	0.0977
100	100	1	0
1,000	10	0.999023	0.0977
1,000	100	1	0

Assuming the bug manifests when that bit takes one particular value. Ten seeds give a 99.9 % chance of exposing it and a hundred make it negligible — and seeds are the cheapest thing in a regression. The column does not depend on the flop count because the question is about one specific dependence, which is the case the bug actually is.

X42.3 Power-up: the sequence and what it must guarantee

Table 384. The power-up sequence, and what breaks if a step is skipped

Step	Guarantee	If skipped
Supplies ramp in the specified order	No forward-biased junction, no latch-up	Permanent damage, not a functional failure

Step	Guarantee	If skipped
Reset asserted before and during ramp	No spurious activity, no contention on shared buses	Bus contention, high current, possible damage
Clocks stable before reset release	Synchronous de-assertion works	The synchroniser has no clock, so de-assertion is asynchronous after all
Reset held for the specified number of cycles	Every flop in every domain has seen an edge	Partially reset state — X42.1
PLL locked before its output is used	Frequency is what the timing assumed	Logic clocked far outside its timing corners
Fuses and trim loaded	Calibration applied	Analogue blocks at their untrimmed operating point
Only then: release to software	A defined starting state	An intermittent boot failure — the hardest class of bug to debug

Worked example 52. How many reset cycles does a block need?

Given. A block with three clock domains at 500 MHz, 100 MHz and 32 kHz, each with a two-flop reset synchroniser.

Method. Reset must be held long enough for the slowest domain to see the required edges, not the fastest — and this is the number a datasheet must state.

Fastest domain period	2 ns
Slowest domain period	30.518 μs
Edges needed per synchroniser	3
Hold time for the 500 MHz domain	6 ns
Hold time for the 32 kHz domain	91.553 μs
Required reset assertion	91.553 μs — set by the slowest domain
Common error	specifying it in cycles of the fast clock

How this is got wrong. By quoting the reset requirement in clock cycles without saying which clock. ‘Assert reset for 16 cycles’ is ambiguous in a multi-clock block and is wrong by four orders of magnitude if the reader picks the fast clock. **State the requirement in absolute time, and state it for the slowest clock the block can be configured with** — including the case where a clock is stopped, which requires either that reset be held until it starts or that the domain be reset asynchronously and independently.

Problem. Your block occasionally fails to come out of reset, roughly one boot in a thousand. Where do you look?

Solution. The frequency is the clue: one in a thousand is a race, not a logic error, because a logic error would be deterministic. Three candidates, in order. **Reset de-assertion recovery:** if any domain's reset is not synchronised, de-assertion races the clock and metastability resolves the wrong way occasionally — the rate is computable from Part X3's MTBF formula with the reset edge as the asynchronous event, and one in a thousand boots is entirely consistent with an unsynchronised reset. **Clock-before-reset ordering:** if reset is released in the same window that a PLL locks or a clock gate opens, some flops see edges and some do not, giving the partial-reset state of X42.1; this shows a dependence on temperature or supply, because they change the lock time. **An uninitialised state element that is usually benign:** a flop without reset whose value normally does not matter, except in the rare case — and this is what random-initialisation regression is for. **The diagnostic that separates them is to vary the reset pulse width and the clock start time:** a recovery race moves with clock phase, an ordering problem moves with pulse width, and an uninitialised value moves with neither.

X43. Power Intent: Domains, Retention and Isolation

Power gating is the only technique that attacks leakage to near zero, and it is the one that changes an IP block's interface, its reset behaviour and its verification plan. A vendor whose block supports it properly is selling something materially different from one whose block does not.

Isolation cells clamp every signal leaving the switched domain.
Without them, a floating input burns static current in the domain that is still on.

Figure 49. A switchable power domain and the cells that make it safe.

X43.1 The four special cells, and what each prevents

Table 385. Low-power cells

Cell	Sits	Prevents	Cost
Isolation	On every signal leaving a switched domain	A floating value driving the always-on domain , which causes static crowbar current in the receiving gate	One gate per signal, plus the enable's routing
Level shifter	Between domains at different voltages	A low-voltage 1 failing to turn off a high-voltage PMOS — again static current	One cell per signal; slower than a buffer
Retention flop	Replacing flops whose state must survive	Losing state on power-down	20–30 % larger than a normal flop, plus always-on routing for the save/restore signals
Power switch	Between the always-on rail and the domain	—	Area, and IR drop through the switch when on ; the switching itself is an inrush event (Part X32)
Always-on buffer	On signals crossing a domain that is off	A signal path being cut	Special placement

Worked example 53. Is retention worth it, or should the block re-initialise?

Given. A block with 20 000 flops, of which 3 000 hold configuration and 17 000 hold datapath state. Leakage when on is 12 mW. The alternative to retention is for software to rewrite the configuration on wake.

Method. Compare three options on area, wake latency and residual leakage. Retention flops still leak, because their storage is always on.

Retain everything: retention flops	20,000
Area penalty at 25 %	5000 flop-equivalents
Residual leakage (retention cells stay powered)	1.8 mW (~15 %)
Retain configuration only	3,000 retention flops
Area penalty	750 flop-equivalents
Residual leakage	0.36 mW
Retain nothing: software rewrite	0 retention flops
Wake latency added	thousands of register writes over APB
Best for a block woken rarely	retain configuration only

How this is got wrong. By retaining everything because it is simplest. Datapath state is usually worthless across a power-down — the block was idle, so there is nothing in flight — and retaining it costs area and leakage for nothing. **The design work is to partition state into what must survive and what must not**, and then to make the latter's reset unconditional so that a wake-up is indistinguishable from a cold start. That partition is a specification item and is the single most useful thing a vendor can document about power behaviour.

X43.2 What UPF adds, and why RTL alone is not enough

Why power intent lives outside the RTL

	Step	Justification
1	RTL describes function; it has no notion of a supply.	<i>A Verilog module does not say which rail powers it.</i>
2	Power domains, switches, isolation and retention are <i>structural</i> and depend on the floorplan and the process.	<i>The same RTL is used with and without power gating in different products.</i>
3	So they are described in a separate file — UPF or CPF — that the tools read alongside.	<i>Synthesis inserts the cells, verification simulates the power states, and place-and-route builds the switch network.</i>
4	Simulation must then model a powered-down domain as X, and check that isolation is enabled before power goes away.	<i>This is the verification that cannot be done in RTL alone, and it is where the bugs are.</i>
5	The power state table enumerates the legal combinations of domain states.	<i>And the illegal ones are what must be proven unreachable — a formal problem of exactly the kind Part X33 recommends.</i>

Table 386. Power-state space against domain count

Switchable domains	Combinations	Typically legal states	Illegal states to exclude	Ordered transitions
2	4	3	1	12
3	8	4	4	56

Switchable domains	Combinations	Typically legal states	Illegal states to exclude	Ordered transitions
4	16	5	11	240
5	32	6	26	992
6	64	7	57	4,032

The legal column assumes a simple nested hierarchy — each domain requires the ones below it. **The transition column is the verification burden**, and it is quadratic, which is why power-state machines are kept deliberately simple and why a block that demands its own independent domain is expensive to integrate.

The classic power-gating bug is an isolation enable that arrives too late, and it is not a functional bug in the usual sense. If power is removed before isolation is enabled, the outputs float for a short interval; downstream gates in the always-on domain then sit at an intermediate level and conduct, drawing a current spike that is invisible to functional simulation and shows up as excess power or, in the worst case, as damage. **The sequence is: assert isolation, assert retention save, then remove power — and the reverse on wake.** Getting it right is a small state machine; proving it right requires power-aware simulation, and asserting it is what a UPF-aware formal check does. An IP block that supplies its own power-control sequence and the assertions that check it is removing a whole class of integration risk.

X43.3 DVFS: the controller and its constraints

Table 387. A DVFS operating-point table, normalised to the top point

V (V)	f (MHz)	Relative power	Relative energy per operation	Relative throughput	Power per unit throughput
0.9	1,200	1	1	1	1
0.8	1,000	0.6584	0.7901	0.8333	0.7901
0.7	800	0.4033	0.6049	0.6667	0.6049
0.6	600	0.2222	0.4444	0.5	0.4444
0.5	400	0.1029	0.3086	0.3333	0.3086

Energy per operation falls monotonically as voltage drops (the V^2 term), which is Part X7's result in the form a system actually uses. The last column is what a governor optimises when the work must be finished by a deadline rather than as fast as possible.

Problem. Why is ‘race to idle’ sometimes better than running slowly, when X43.2 shows energy per operation is lowest at low voltage?

Solution. Because the block is not the only thing consuming power. Running at the top operating point finishes the work sooner and lets the *whole subsystem* — memory, interconnect, PLLs, the always-on logic, and any peripheral waiting on the result — enter a low-power state earlier. That static and shared component does not scale with the block's voltage, so the comparison is between (fast, high dynamic, short time, then everything off) and (slow, low dynamic, long time, everything on throughout).

Race to idle wins when the fixed overhead per unit time is large relative to the block's own dynamic power, which is common in small IP blocks inside large systems and uncommon in a block that dominates its chip. **The crossover is computable** from the block's dynamic power at each point, the platform's idle power, and the entry/exit energy of the low-power state — and it is worth computing rather than asserting, because both answers appear in the literature and both are right for their own systems.

Z1. The Two-Member IP Team: You and the Agent

This volume is written for a specific arrangement: one engineer and one automated verification agent, producing IP that is good enough to sell. That is a smaller team than any company would assign to the job, and it can work — but only if the division of labour is decided deliberately rather than by what happens to be convenient. This part sets it out, and every claim about the agent in it is measured by running the agent while this page is rendered.

The division is not by difficulty. It is by whether a decision is needed.

The agent does what is checkable; you do what is judgeable.

Figure 50. The division of labour. Everything on the right is mechanically checkable; everything on the left needs a judgement.

Z1.1 The rule that decides who does what

Why the boundary falls where it does

	Step	Justification
1	The agent can only act where there is an oracle — something that says right or wrong without a human.	<i>A golden model, a standard's test vectors, a compiler, a timing report.</i>
2	Where an oracle exists, the agent's work is <i>search plus check</i> , and search with a good oracle is reliable and improves with compute.	<i>This is the regression, the shrink, the repair attempt and the mutation score.</i>
3	Where no oracle exists, any output must be read by a human, and the failure mode is work that looks right.	Which is the expensive kind of failure , because it is found late.
4	So: the agent owns everything downstream of a model; you own the model and everything upstream of it.	<i>Reading the specification, deciding what the block should do, deciding which side of a disagreement is wrong — none of these has an oracle.</i>
5	The corollary is where to invest: make the oracle better and the agent gets better for free.	<i>A stronger golden model, a wider stimulus, a throughput bound, a lint rule — each one extends the region the agent can work in, permanently.</i>

Table 388. Task by task, and why

Task	Who	Because
Read the standard, resolve ambiguities	You	No oracle; and the ambiguities are what you will be asked about
Write the bit-accurate golden model	You	It is the oracle. Writing it is how you find out what the specification actually says
Choose the architecture, the word lengths, the parallelism	You	Judgement against cost; Parts X1–X2 give the arithmetic
Write the RTL	You	For now. The agent repairs small defects; it does not architect
Run the regression on every seed, all night	Agent	Pure search against an oracle
Reduce a failure to one stimulus	Agent	Mechanical, and it is the difference between a debuggable and an un-debuggable report
Attempt a single-edit repair	Agent	Bounded search; three gates bound the false-accept rate
Measure the mutation score	Agent	The number that says whether the suite bites — and the escapes say where the stimulus is thin
Measure throughput against a stated bound	Agent	A value-only regression cannot see a block getting slower
Decide whether an escape is an equivalent mutant	You	A machine cannot decide behavioural equivalence in general
Decide which side of a disagreement is wrong	You	Only the specification settles it, and only you have read it
Talk to the customer, price the work, scope it	You	Part Y5

The temptation to let the agent write the model is the one thing that destroys the arrangement. If the model and the RTL come from the same process, they share its misunderstandings and their agreement proves nothing — this is the independence argument of Part Y11, and it does not change because one of the two authors is a machine. The agent may write *stimulus*, may write *checkers derived from the model*, and may repair RTL; it must not be the source of the reference. **Your reading of the specification is the asset the business is built on**, and it is the one part that cannot be delegated.

Z1.2 What the agent actually does, measured now

Table 389. The agent's blocks, run while this page was rendered

Block	Checker bites?	Stimuli	Mismatches	Distinct outputs	Throughput bound?	Wall time
crc32_8	yes	600	0	599	—	0.021 s
crc32_stream	yes	31	0	31	yes	0.0235 s
gf_mul	yes	600	0	444	—	0.0197 s
regfile	yes	600	0	78	—	0.0238 s
rs_syn_step	yes	600	0	458	—	0.0186 s

Run with Icarus Verilog at build time. **The ‘checker bites’ column is produced by deliberately corrupting a golden value and asserting that the comparison notices** — without it the mismatch column would be an unexamined green light.

Table 390. Mutation score, measured at build time

Block	Mutants run	Caught	Score (%)	Escapes	Time
crc32_8	6	6	100	0	8.1 s

Block	Mutants run	Caught	Score (%)	Escapes	Time
crc32_stream	8	8	100	0	8.3 s
gf_mul	6	6	100	0	8.1 s
regfile	13	13	100	0	0.4 s
rs_syn_step	6	6	100	0	8.1 s

Each mutant is a single-token edit to the DUT — not to the testbench, and not inside a comment, because mutating either produces escapes that mean nothing. **An escape is a finding, not a defect in the score:** it is either an equivalent mutant or a place the stimulus does not reach, and both need a human to say which. **Every block reads 100 % with zero unjudged escapes, which is the state the release gate of Part Z3 requires** — a column that is constant because the bar was met, not because the measurement is stuck. It was not always so: the register file scored 58.3 % until the escapes were read.

Z1.3 A worked morning: what the escapes actually told us

The mutation score is not a grade; it is a pointer. The following happened while this book's own register-file block was being built, and it is the clearest illustration in the book of why the number is worth measuring.

Table 391. From a score to two real bugs

Step	What happened	What it cost
Regression written, all green	400 APB accesses, no mismatch	—
Mutation score run: 58.3 %	Five escapes, all pointing at the same place	20 minutes
Escapes read	$r \mid hw_set \rightarrow r \wedge hw_set$ not caught — because <code>hw_set</code> was tied to zero, and 0 behaves identically under both	The W1C and RC paths had never executed
Testbench fixed to pulse the hardware inputs	Plus a directed sequence: set three bits, read, clear one, check the other two survive	an hour
Regression re-run: two failures	Both were real generator bugs — an ID register that could not hold a constant, and an RC register cleared during the APB setup phase because <code>penable</code> was missing from the read term	—
Fixed, re-scored	100 % (13 of 13)	Two bugs that would otherwise have been found by a customer's driver

Graduate · Note what the green regression was worth before the mutation score ran. It was not wrong — those 400 accesses really did match — and it was nearly worthless, because the stimulus never reached the logic that was broken. **This is the difference between ‘the tests pass’ and ‘the tests would fail if the design were wrong’**, and only the second is evidence. For a one-person house it is also the only affordable substitute for a verification team's scepticism: you cannot review your own work with fresh eyes, and the mutation score does not need fresh eyes.

Problem. You are one person. How much of the day should go to verification?

Solution. More than feels reasonable, and the arithmetic from Part Y1's effort table says roughly how much: verification and everything downstream of RTL is about three quarters of the work in a sellable block. But the useful answer for a day rather than a project is a **shape**, not a fraction. **Verification infrastructure is built once and runs forever**, so it belongs early and its cost is amortised; **the agent runs it while you sleep**, so the marginal cost of *running* verification is zero and only the marginal cost of *improving* it is real. That changes the allocation: spend your hours on the golden model, the stimulus and the checkers — the things that decide what the agent can catch — and almost none on running or triaging, which the agent does. **A practical daily target is that every session leaves the oracle stronger than it found it:** one more property checked, one more corner in the stimulus, one more bound measured. That compounds, and it is the only thing in a one-person house that does.

Z2. The Daily and Weekly Loop

A two-member team has an unusual property: one member works when the other does not. That makes the shape of the day the main scheduling decision, and getting it right is worth more than working longer.

The agent works the interval you are not there.
Your afternoon decides what it is able to find that night.

Figure 51. One day.

Z2.1 The day

Table 392. Four slots, and what each is for

When	You do	Why then	What it must not become
Morn- ing	Read the night's ledger. Triage: real failure, equivalent mutant, infrastructure noise. Apply or reject the proposed patches.	The information is freshest and the decisions unblock the rest of the day	Debugging. Triage decides <i>what</i> to debug; the debugging happens midday
Midday	The work that needs an unbroken stretch: the golden model, architecture, RTL, the hard bug from triage.	It is the only slot long enough	Email, or fiddling with the flow
After- noon	Strengthen the oracle: one more property, one more corner in the stimulus, one measured bound, one lint rule.	This is what decides what the agent can catch tonight	Optional. It is the compounding part and it is always the first thing sacrificed
Even- ing	Launch the run and stop. Check it is alive, not that it is finished.	The agent has the night	Watching it. If you are watching, the ledger is not good enough

```

The evening command, and the morning one
# 저녁 -- 밤새 돌린다 (setsid/nohup/disown; 확인은 pgrep)
bash edu/agent/run.sh 12

# 아침 -- 무엇이 있었나
bash edu/agent/status.sh
python3 edu/agent/mutscore.py          # 주 1회면 충분하다

# 밤새 빨간불이 났다면: 최소 사례와 제안된 편집이 원장에 있다
grep '빨간불' edu/agent/ledger/regress.jsonl | tail -5
  
```

The failure mode of this loop is that the afternoon slot disappears. It is the only slot with no immediate consequence — skip it and tonight's run still happens, this week's deliverable still moves — so it is the one that gets spent on whatever is urgent. Three weeks later the agent is finding nothing, not because the design is clean but because the oracle stopped growing

while the design kept growing. **The measurable symptom is a flat mutation score against a rising line count**, and it is worth plotting: if the design grew 30 % and the mutant count did not, the suite is covering a smaller fraction of it than it was.

Z2.2 The week

Table 393. The week

When	What	Why
Monday	Plan against the deliverable list; pick this week's one thing	A week with two goals finishes neither
Tuesday–Thursday	The daily loop	—
Friday morning	Mutation score across every block; read every escape	Weekly is the right cadence — daily is noise, monthly is too late to act on
Friday afternoon	Documentation for what changed this week	Written now it takes twenty minutes; written at release it takes days and is wrong
Friday, last thing	Tag, and run the full gate from a clean checkout	A green working directory is not a green repository — the commit may be missing a file

The Friday items are the ones that make a release possible without a release scramble. **Both are cheap weekly and expensive in a batch**, which is the general shape of everything in this chapter.

Worked example 54. What a night is actually worth

Given. The agent runs 12 hours. Each block's regression takes about 0.02 s of simulation per 600 stimuli, and a full mutation pass over five blocks takes about a minute.

Method. Count what the night can cover, then note what limits it — which is not the machine.

Regression rounds per hour (order)	10^5
Distinct seeds consumed in 12 hours	$\approx 10^6$
Mutation passes possible in one night	hundreds
Engineer-hours consumed	0
What actually limits the value	the stimulus distribution and the golden model
Marginal value of the 500th mutation pass	zero
Marginal value of one new checker	large and permanent

How this is got wrong. By measuring the night in rounds. A million rounds of the same distribution explore the same region a thousand times — Part X8's coupon-collector arithmetic says the return flattens far below that. **The honest use of the night is variety, not volume:** rotate the constraint sets, replay every previous minimal reproducer as a growing regression, and run the mutation pass. A loop that only turns the seed stops learning within the first hour and then keeps the machine warm until morning.

Z2.3 Triage: what to do with each thing in the ledger

Table 394. The morning decision table

Ledger says	You do	Time
초록 on every block	Nothing. Read the mutation trend instead	1 min

Ledger says	You do	Time
자해검사 failed	Stop. The night's results mean nothing. Fix the harness first	Highest priority — a broken checker is worse than a broken design
자극이 DUT 를 안 건드렸다	The stimulus degenerated — a constraint is over-tight or a parameter is wrong	10 min
빨간불 -- 수리 적용 됨	Read the patch. It passed three gates; it still has to be right for the right reason	5 min per patch
빨간불 -- 수리 후보 있음 (적용 안 함)	The agent found an edit and was not allowed to apply it. Decide	5 min
빨간불 -- 수리 실패	This is the real work. The minimal reproducer is in the ledger; it is outside the repair library, which usually means it is structural	The morning's budget goes here
적용했다가 되돌림	The edit passed the first seeds and failed after application — look at why, it is usually an interacting change	15 min
An escape in the mutation report	Equivalent mutant, or a hole in the stimulus. Write down which, and the reason	5 min each, weekly

Graduate · **Record the verdict on every escape, permanently.** An escape you have judged to be an equivalent mutant will reappear in every run forever, and re-deciding it each week is both wasted time and an invitation to stop reading the list. Keep a file of judged escapes with the reason — ‘extra loop iteration reads an out-of-range bit, which is x, so the branch is never taken’ — and have the report mark them as known. **What must not happen is suppressing them silently:** a suppressed escape whose reasoning was wrong is a permanent blind spot, and the file is the thing that lets a reviewer, or you in six months, check the reasoning.

Problem. The agent applied a patch overnight and the regression is green. Do you trust it?

Solution. Trust the *evidence* and check the *reason*, which are different things. The evidence is strong: the edit passed the original seed, passed a seed never used during the search (the overfitting gate), and passed the self-check confirming the comparison still bites. That rules out the classic automated-repair failure of special-casing the failing input. **What it does not establish is that the edit is the change a human would have made.** An edit that makes the symptom go away by tightening a condition can be correct on every stimulus the suite has and wrong in a case the suite does not reach — and if the suite reached that case, the bug would have been caught before the patch. So: **read the diff, and ask what the original defect was.** If you can state the defect in one sentence, keep the patch. If you cannot, the patch is masking something and the right response is to extend the stimulus until the failure is understood. **Five minutes per patch, and it is the five minutes that keeps the arrangement honest.**

Z3. The Quality Bar: What 'Sellable' Means as Numbers

'Industry level' is not a feeling. A customer's technical evaluation is a list of questions with numerical answers, and a block either has them or does not. This part is that list, with the acceptance criterion for each and the command that produces it. **A block that passes every row is sellable; one that passes most of them is a prototype.**

Z3.1 The gate list

Table 395. The gates a sellable block passes

Gate	What it asserts	How it is measured	Why
Functional agreement	Zero mismatches against an independent golden model, on many seeds	agent: <code>잔다() 틀림 == 0, ≥ 20</code> seeds	Non-negotiable
The checker bites	Corrupting a golden value makes the comparison fail	<code>자해검사() == True</code> every run	Without it the row above is meaningless
Stimulus is non-degenerate	The golden model produced many distinct outputs	<code>서로다른출력 ≥ 2</code> , in practice > 20	A constant stimulus passes any design
Mutation score	Injected defects are caught	<code>mutscore.py ≥ 90 %</code> , every escape judged in writing	The number a knowledgeable buyer asks for
Throughput	Cycles per unit of work within a stated bound	<code>성능한계()</code> declared and met	A value-only suite cannot see a block getting slower
Code and toggle coverage	Every line and every bit exercised	Verilator or a coverage-capable simulator	Weakest of the metrics; necessary, not sufficient
Lint clean	No inferred latches, no width mismatches, no incomplete sensitivity	<code>verilator --lint-only -Wall</code> , zero warnings or a written waiver	The customer will run this and judge you by it
Synthesises	To a gate netlist, with reported area and frequency	<code>yosys</code> plus a timing run, scripts shipped	An unsynthesisable block is not a product
CDC analysed	Every crossing identified, structured and constrained	A CDC tool, or a documented manual analysis with the constraints	The commonest integration failure
Reset verified	Random initialisation, many seeds; de-assertion synchronised per domain	Regression with randomised initial state	The commonest silicon failure
Register map generated	RTL, header, docs and IP-XACT from one source	<code>house/regmap.py --전부</code>	Hand-maintained copies diverge
Documentation	Datasheet, integration guide, known issues, release notes	They exist and match the code	Support cost is inversely proportional to this
Reproducibility	A clean checkout reproduces every number	<code>scripts/precheck.sh</code> from HEAD, not the working directory	A missing file passes locally and fails for the customer

Nine of the thirteen are runnable by the agent, unattended. The four that are not — judging escapes, CDC analysis, documentation, and deciding what the block should do — are the ones this volume says belong to you.

The bar is not 'no known bugs'; it is 'here is the evidence, and here is what is not covered'. Every real IP block ships with limitations, and Part Y5 argues that naming them is what distinguishes a professional supplier. The gate list above is

what converts that from a posture into a document: each row either passes, or fails with a stated reason and a workaround. **A customer can evaluate that. They cannot evaluate an assurance.**

Z3.2 Running the whole bar in one command

A gate that requires remembering to run it is a gate that will be skipped in the week it matters. The repository's own discipline applies: one command, from a clean checkout, that runs everything and refuses to report green on anything it could not check.

```
edu/house/release.sh — the release gate
bash edu/house/release.sh <블록이름>

1. 깨끗한 판을 꺼낸다          -- 작업 디렉터리를 안 본다
2. 자해검사                   -- 비교가 무는가
3. 회귀 (씨앗 20개)           -- 값과 순서
4. 성능                       -- 선언된 한계 안인가
5. 변이 점수                   -- 몇 %, 탈출은 몇 개
6. lint (verilator -Wall)
7. 합성 (yosys)               -- 면적과 셀 수
8. 레지스터 맵 생성물         -- 컴파일되는가
9. 문서가 있는가              -- 데이터시트·통합가이드·알려진문제
10. 보고서를 낸다             -- 통과/실패와 **못詹 것**을 같이

**못詹 것을 초록이라고 하지 않는다.**  도구가 없으면 '없어서 못詹다' 로 낸다.
```

Worked example 55. What the gate costs to run

Given. Five blocks, the regression at 20 seeds each, a mutation pass, lint and synthesis.

Method. Estimate from the measured per-step times in this book's own runs.

Regression, 600 stimuli	0.03 s per seed per block
20 seeds × 5 blocks	3 s
Self-check	0.15 s
Mutation pass, 5 blocks	≈60 s
Lint	seconds
Synthesis	seconds to minutes per block
Whole gate	a few minutes
How often it should run	every push, and nightly

How this is got wrong. By assuming the gate is expensive and running it at release. At a few minutes it is cheap enough to run on every push, and a gate that runs on every push finds the regression on the commit that caused it rather than three weeks later. The expensive parts — a full mutation pass over a large block, a long synthesis — belong in the nightly run, which costs nothing at all because nobody is waiting.

Z3.3 What the numbers should look like

Table 396. Acceptance thresholds: internal and at release

Metric	Internal (keep working)	Release	Note
Mismatches	0	0	Any non-zero is a stop
Self-check	passes	passes	A failure invalidates the run

Metric	Internal (keep working)	Release	Note
Distinct outputs	> 20	> 20	Low means the stimulus degenerated
Mutation score	≥ 90 %	≥ 95 %	Escapes all judged and recorded
Escapes unjudged	0	0	An unjudged escape is an unexamined hole
Lint warnings	0	0	Or a written waiver per warning
Coverage (line)	> 95 %	> 99 %	Unreached lines explained
Throughput margin	> 10 %	> 20 %	Against the declared bound
Documented registers	100 %	100 %	Generated, not typed
Known issues listed	yes	yes	Absence is not a clean sheet

Two columns because they serve different purposes. The internal column is what you refuse to go home below; the release column is what a customer's evaluation will find. Setting the internal bar lower than the release bar is how a release becomes a scramble.

Problem. A customer's technical evaluation asks for your verification plan. What do you send?

Solution. Not a narrative. Send four things, and their existence is most of the answer. **The gate list of Z3.1 with each row's current value** — this is a table of facts and it is what they are actually trying to establish. **The mutation report, escapes included**, because it is the one artefact that demonstrates the suite bites rather than merely runs, and very few suppliers have one; including the escapes with their judgements is more convincing than a higher score without them. **The known-issue list**, dated, with workarounds. **And the command they can run themselves** on the delivered package to reproduce every number. **The fourth is the one that converts the first three from claims into evidence**, and it is the reason the release gate must run from a clean checkout rather than from your working directory — if it only works on your machine, they will find that out, and it will cost more than the bug it hides.

Z4. The Deliverable Pack, Built and Gated

Part Y5 lists what a customer receives. This part builds it. Every artefact named here exists in this repository, every generator named here runs, and the gate that checks them is run while this page is rendered. A book that describes a deliverable pack without producing one is teaching the habit it warns against.

Z4.1 What is in the repository

Table 397. The pack, with line counts read from disk at build time

File	What it is	Lines
edu/house/regmap.py	한 맵에서 RTL · C 헤더 · 문서 · IP-XACT 를 낸다	387
edu/house/release.sh	판매 가능 관문 전체를 한 번에 돌린다	188
edu/house/DATASHEET.md	데이터시트 (젠 수와 그 조건)	72
edu/house/INTEGRATION.md	통합 가이드 (전화하지 않고 끝낼 수 있게)	62
edu/house/KNOWN_ISSUES.md	알려진 제한 (없다고 적지 않는다)	27
edu/agent/harness.py	골든모델 대 RTL, 자해검사와 처리량 포함	186
edu/agent/mutscore.py	변이 점수 -- 검사가 무는지를 수로	165
edu/agent/vrepair.py	한 곳 편집 수리, 과적합 관문 포함	195
edu/agent/agent.py	밤새 도는 고리	196
tests/test_verif_agent.py	에이전트를 실제로 돌려 보는 검사	279
tests/test_release_gate.py	**관문 자체를 망가뜨려 보는 검사**	123

Counted by reading the files as this page was rendered. A row showing zero would mean the book is describing something that does not exist, which is the failure this table is designed to make visible.

Z4.2 One source, four outputs — measured

Table 398. Generated from one map of 7 registers and 16 fields

Output	Lines	Characters
RTL (Verilog)	101	4,575
C header	99	5,554
Markdown (datasheet section)	78	2,316
IP-XACT	186	8,962

Generated at build time. Part Y10 computed that maintaining six copies by hand over a nine-month project has an expected nine missed edits; the generator is a day's work and removes all nine.

Graduate · The map validates itself, and that is most of the value. The definition refuses overlapping bit ranges, offsets that are not word-aligned, reset values too wide for their field, unknown access types, duplicate offsets, and — the one that matters most — a hardware-written field declared RW, which is the read-modify-write race of Part Y10. **Each of those is a defect that a hand-written map produces regularly and that nothing downstream detects:** the RTL compiles, the header compiles, the documentation looks right, and the bug appears in the customer's driver.

24.3 What the gate says today

Table 399. The release gate, run while this page was rendered

Block	Passed	Failed	Unmeasured	Mutation score	Cells (yosys, open library)
crc32	7	0	0	100.0 %	216
crc32_stream	7	0	0	100.0 %	1,983
gf_mul	7	0	0	100.0 %	208
regfile	7	0	0	100.0 %	419
rs_syndrome	7	0	0	100.0 %	218

Totals: 39 passed, 0 failed, 0 unmeasured. The cell counts are from an open-source synthesis flow and an open library; **they are not an area figure in any customer's process**, and Part Y14's rule says to present them with that stated rather than to quote a bigger number without it.

24.4 Three generator bugs the gate found

The register-map generator was written from Part Y10's argument and looked correct. The agent and the gate found three defects in it, none of which any amount of reading would have found, and each is instructive about a different failure mode.

Table 400. What was found, and by which gate

Bug	Found by	Why reading would not have found it
An ID register could not hold a constant. Every RO field was wired to a hardware input, so a vendor code read as zero	The regression, against an independent model	The generator was internally consistent — it did exactly what its author intended, and the intention was incomplete
A read-clear register cleared during the APB setup phase. rd was psel & ~pwrite, missing penable	The regression, after the stimulus was extended	It reads as correct; the defect is in the protocol's two-phase timing, which only a running comparison exposes
A software-set field had an unused hardware port. W1S defaulted to hardware-driven, which is wrong for the common case	verilator -Wall (UNUSED SIGNAL)	An unused port is harmless functionally and is a question the integrator has to ask you

And the mutation score found the stimulus hole that hid the second one. Before it ran, the register-file regression was green on 400 accesses and scored 58.3 %. Five escapes all pointed at the same place: the hardware-side inputs were tied to zero, so the W1C and RC paths had never executed. Driving them turned up two real failures within minutes. **The green regression was not wrong — those 400 accesses did match — and it was nearly worthless.** That distinction is the whole argument for measuring whether a suite bites rather than whether it passes.

Problem. You have one week before a customer evaluation. What do you build first?

Solution. Not more features. Build, in this order, the things the evaluation will actually test. **First the gate**, because everything else is easier to trust once one command produces the numbers; a day. **Then the mutation score**, because it is the single artefact that distinguishes you from a supplier who says ‘we tested it thoroughly’, and because it will find the stimulus holes you do not know about; half a day plus whatever it turns up. **Then the known-issue list**, which costs an afternoon and is read as competence rather than as weakness. **Then the integration guide**, written as if for someone you will never speak to. **Only then the datasheet**, because by that point every number in it exists and is reproducible — which means writing it takes an hour instead of a day and none of it is invented. **A week spent this way produces a smaller block that can be bought; a week spent on features produces a larger one that cannot.**

Z5. Choosing the First Product, Concretely

Part Y8 gives the criteria. This part applies them to real candidates with weights chosen for a one-person house, and arrives at a recommendation — including the one column that is currently zero for every candidate, which is the honest headline.

Z5.1 The scorecard

Table 401. Criteria and weights for a one-person house

Criterion	Weight	Why this weight
규격을 구할 수 있나	3	못 구하면 못 만든다. 끝
독립 골든모델이 있나	3	혼자 검증하는 유일한 길
소프트 IP 인가	3	하드 매크로는 아날로그와 공정 접근이 필요하다
표준이 바뀌는 중인가	2	기존 공급자의 블록이 낡는다 -- 들어갈 틈
공급자가 적은가	2	많으면 가격으로 진다
가족으로 번지나	2	둘째 셋째가 싸진다
이름 델 고객이 있나	3	없으면 투기다
검증이 기계화되나	2	에이전트가 밤새 할 수 있나

Weight 3 means a zero here kills the candidate regardless of the rest. A larger company would weight ‘specification obtainable’ at 1, because a membership is a rounding error in its budget; for one person it is a gate.

Table 402. Scored 0–3 per criterion, weighted; maximum possible 60

Candidate	규격 을...	독립 립...	소프 트...	표준 이...	공급자 가...	가족으 로...	이름...	검증 이...	Total	Note
RS-FEC (KP4) 복호기	1	3	3	3	2	3	0	3	43	규격 조문(Clause 91)을 아직 못 봤다 -- 그것이 1번 걸림돌
AES-GCM 엔진	3	3	3	0	0	2	0	3	37	규격도 시험벡터도 공짜인데 **공급자가 너무 많다**
ML-KEM (Kyber) NTT 코어	3	3	3	3	3	2	0	3	49	규격 공개, 참조 구현 공개, 표준이 막 확정, 공급자 적음
MIPI CSI-2 수신기	1	1	2	1	1	2	0	2	24	규격이 유료 회원제, PHY 가 하드 매크로 -- 1인에게 무겁다
이더넷 PCS (802.3dj 내부코드)	1	2	3	3	3	3	0	3	42	소프트·바뀌는 중·공급자 적음. 규격 조문이 다시 걸림돌

Scores are judgements, and stating them as numbers is what makes them arguable. A reader who disagrees can change one cell and see whether the ranking moves — which is the point of a scorecard and the reason it beats a paragraph of reasoning.

Graduate · On these weights the winner is ML-KEM (Kyber) NTT 코어, and the reason is worth reading off the table rather than taking on trust: it is the only candidate that scores 3 on *all four* of specification availability, independent golden model, soft RTL, and a changing standard with few suppliers. The post-quantum transition put a new, fully public, algorithmically demanding block into a market whose incumbents built their portfolios around RSA and ECC. **And Part X6's entire FFT analysis transfers to the NTT** — same radix choices, same twiddle symmetries, same memory-versus-multiplier trade, with modular arithmetic replacing complex arithmetic. A team that has built an FFT has most of it.

Every candidate scores zero on ‘a customer you can name’, and that is the real finding. The scorecard ranks technical and market fit; it cannot manufacture demand. Six good rows and a zero in that column describes a project, not a business. **The action the table implies is not to start building the winner — it is to spend the next two weeks turning that column into a non-zero**, by talking to people who buy this kind of block, and to let what they say re-score the other rows. A candidate that scores 40 with a named customer beats one that scores 48 without.

25.2 Sizing the winner before committing

Worked example 56. What an NTT core costs to build, estimated from the structure

Given. ML-KEM uses a 256-point NTT over the prime $q = 3329$, so coefficients are 12 bits and the modulus is small. Compare against the FFT arithmetic of Part X6.

Method. Count butterflies, multipliers and memory the same way Part X6 does, then convert to weeks with Part Y8's plan.

Transform size	256
Stages (radix 2)	8
Butterflies per transform	1,024
Coefficient width	12 bits
Modular multiplier (12×12 then reduce)	small — a few hundred gates
Coefficient memory	384 bytes
Twiddle ROM (128 entries)	192 bytes
Compared with a 4096-point complex FFT	two orders of magnitude smaller
Plausible effort from Part Y8's plan	half of the 39 weeks — the block is small, the verification is not

How this is got wrong. By sizing the arithmetic and forgetting that the verification does not shrink with the datapath. The core is small; the golden model, the known-answer vectors from the standard, the constant-time argument (Part X36), the register map, the documentation and the release gate are the same work they would be for a block ten times larger. **That asymmetry is good news for a first product** — it means a small block can carry a full-quality wrapper, which is exactly what a first product needs to demonstrate.

25.3 The two weeks before you write any RTL

Table 403. Two weeks, and what each part produces

When	What	Why it is in this order
Day 1–2	Prior-art note (Part Y6): closest work, how we differ, queries run, **where we have not looked**	Committed before any code — the repository's own rule
Day 3–5	Read the standard; write down every ambiguity	The ambiguity list is your first deliverable and your first sales document
Day 6–8	Golden model in Python, checked against the standard's known-answer vectors	If the vectors do not match, you have misread the standard — find out now, not in month four
Day 9–10	Architecture study: word lengths, parallelism, memory (Parts X1, X6)	Produces the area and throughput numbers you will quote
Day 11–12	Talk to three potential customers with the ambiguity list and the architecture study	This is the step that turns the zero column into a number

When	What	Why it is in this order
Day 13–14	Re-score the candidates with what they said	The scorecard was a guess until this point

No RTL in fourteen days, and that is deliberate. Every item above changes what the RTL should be, and each is cheap to redo and expensive to redo after the RTL exists.

Problem. You cannot get three customer conversations. Now what?

Solution. Treat that as data about the market rather than as an obstacle to route around. If nobody will spend twenty minutes discussing a block they might buy, the likeliest explanations are that the block is not a problem they have, that they already have a supplier they are satisfied with, or that you have not found the right people — and the third is the only one that is your mistake to fix. **Widen the search before widening the scope:** the people who answer are rarely procurement; they are engineers, and they are reachable through the standards body's working group, the open-source projects around the protocol, and conference and plugfest attendee lists. **A useful substitute when conversations genuinely cannot be had is a public artefact that attracts them** — the golden model published with the standard's vectors, a note on an ambiguity you found in the specification, a comparison of the open implementations. Part Y6's argument for publishing applies exactly here: it is how a house nobody has heard of becomes findable. **What is not an answer is to start building and hope**, because the 39 weeks are spent either way and only one of the two ends with someone to sell to.

Z6. What the Agent Cannot Do

A tool's limits are more useful than its features, because the limits decide where your attention has to go. This part states the agent's honestly, each with the evidence from this repository's own use of it, and then says what to do about each one.

Z6.1 The limits, named

Table 404. What the agent does not do, and why not

Limit	Why	What you do instead
It cannot decide what the block should do	No oracle exists for a specification reading	You read the standard. This is the asset
It cannot write the golden model	The model <i>is</i> the oracle; a machine-written oracle checked by the same machine proves nothing	You write it, from the standard, before the RTL
It cannot architect	Architecture is a judgement against cost, and the cost model is yours	Parts X1, X2, X6, X13 give the arithmetic; you apply it
Its repairs are single-token edits from a narrow library	A wider library finds something for every failure and most of it is wrong	Structural bugs come to you with a minimal reproducer — which is the valuable part
It cannot judge an equivalent mutant	Behavioural equivalence is undecidable in general	You judge each escape once and record the reason
It does not know what the stimulus is missing	It measures what the stimulus reaches, not what it should reach	The mutation escapes point at the holes — read them
It cannot verify timing, area or power	Those need a library and a flow, not a comparison	The release gate runs lint and synthesis; sign-off is the customer's
It cannot talk to a customer	—	Part Y5. This is most of whether the business works

The limit that does the most damage when forgotten is the second. Under deadline it is very tempting to have the machine write the reference too — it is faster, it looks like the same kind of work, and the result will agree with the RTL. It will agree because both came from the same reading, which is the one thing the reference exists to be independent of. **Every disagreement you delete this way is a check you cannot get back**, and nobody will remember six months later which checks were deleted or why. Part Y11 states the rule for a human team; it does not change when one member is a machine.

Z6.2 What happened when the limits were tested

Table 405. This repository's own record

What the agent did	What it could not do	Who closed the gap
Found the ID-register bug on the first run	It could not say the generator's <i>design</i> was incomplete	A human decided RO fields should default to constants
Found the RC/penable bug after the stimulus was extended	It could not find it before — the stimulus never reached the logic	The mutation escapes pointed at the hole; a human read them
Scored the register file at 58.3 %	It could not say <i>why</i> the five escapes shared a cause	A human read three lines and saw hw_set tied to zero
Repaired three injected Verilog faults exactly	None of the three was a structural bug	— the library is deliberately narrow

What the agent did	What it could not do	Who closed the gap
Caught a throughput-only regression once the bound existed	It could not invent the bound	A human measured the clean block and chose 2.6 cycles/byte
Ran all night, every night, for free	—	This is the part that is genuinely free, and it is not the valuable part

Graduate · Read the last two rows together. The compute is free and the bound is not; the agent contributed the checking and a human contributed the number being checked against. Every one of the agent's real finds in this repository traces back to a human decision about what to compare, what to drive, or what bound to declare. **That is not a complaint about the agent — it is the investment thesis.** An hour spent on the oracle is repaid every night indefinitely; an hour spent running the agent is repaid once and would have happened anyway.

Z6.3 The failure modes of working with it

Table 406. How a two-member team goes wrong

Failure	How it looks	The early symptom
The oracle stops growing	The agent finds nothing and everyone is pleased	Flat mutant count against a rising line count — plot it
Patches accumulate unread	Green regressions, RTL nobody can explain	A patch whose original defect you cannot state in one sentence
Escapes suppressed rather than judged	The score rises and the blind spots stay	A suppression file with no reasons in it
Triage becomes debugging	The morning consumes the day; the afternoon slot disappears	Part Z2's first symptom, and the commonest
Stimulus tuned until it passes	A constraint narrowed to make a failure go away	Distinct-output count falling — the gate checks it for this reason
Believing the mutation score is the goal	Mutants chosen because they are easy to catch	The library stops growing while the score stays at 100 %

Worked example 57. Detecting the first failure mode before it costs a month

Given. Plot, weekly: lines of DUT code, number of mutants generated, mutation score, and distinct outputs in the regression.

Method. Each pair of series answers a question that neither answers alone.

Lines rising, mutants flat	the suite covers a shrinking fraction
Mutants rising, score flat	healthy — new code is being checked
Score rising, escapes flat at zero	healthy
Score 100 %, mutants flat for weeks	the library has stopped growing, not the design
Distinct outputs falling	the stimulus is narrowing
Everything flat	you are not working on this block — fine, if deliberate

How this is got wrong. By watching the score alone. A mutation score is a ratio, and a ratio hides both of its terms: 100 % of eight mutants on a block that has grown to four thousand lines is a much weaker statement than 90 % of two hundred. **Plot the numerator and the denominator**, which costs nothing because the agent already records both, and the failure mode announces itself weeks before it matters.

Problem. Should the agent be allowed to apply its own patches unattended?

Solution. Yes for a narrow class, and the class is worth defining precisely rather than deciding by feel. **Allow it when all four hold:** the edit is a single token from the declared library; it passed a seed never used during the search; the self-check confirms the comparison still bites; and the block is one whose golden model you trust because it is independent. **Refuse it otherwise,** and in particular refuse it on any block whose reference model you wrote by reading the RTL — there the whole gate structure rests on nothing. Two practical additions make the yes safe. Keep the default as report-only (`--적용` is opt-in, which is how this repository ships it), so an unattended night cannot silently change the design. And require that every applied patch be reviewed in the morning with the one question of Part Z2: *what was the original defect?* **If you cannot state it, the patch is masking something,** and the right response is to extend the stimulus rather than to keep the patch.

Z7. Solo Bring-Up: The Bench You Actually Need

At some point a block has to run on real hardware, because a customer will ask whether it has and because simulation does not model the things that break. This part is about the smallest bench that answers that honestly, what it costs, and what it cannot tell you.

Z7.1 What an FPGA prototype proves — and what it does not

Table 407. Claims a prototype supports

Claim	Prototype evidence?	Why
The RTL is functionally correct at speed	Strong	Billions of cycles against real traffic — far beyond simulation
It interoperates with a real partner	Strong, and unobtainable any other way	The partner's implementation is the thing you cannot simulate
Reset and initialisation work	Strong	Real power-up, real clock start — Part X42's untestable cases
The clock-domain crossings are sound	Weak	Metastability at the FPGA's rates and MTBF is not the ASIC's
It meets the ASIC frequency	No	Different fabric entirely. An FPGA number says nothing about an ASIC number and quoting it as if it did is the classic misrepresentation
The area estimate is right	No	LUTs are not gates
Power is acceptable	No	Unrelated
Timing closes at the customer's corners	No	Their library, their flow, their corners

The temptation is to quote the FPGA frequency. It is a real number that was really measured, and it is about a different technology. A customer's evaluator knows this and will read the substitution as either ignorance or misdirection, both of which cost more than the number was worth. **Quote it as what it is:** ‘runs at 200 MHz on *this* part, with this build, and here is the project’, alongside a separately-labelled synthesis estimate with its library named. Part Y14's rule again: the honest smaller claim is more persuasive than the unattributed larger one.

Z7.2 The bench, itemised

Table 408. A first bench, with what each item is for

Item	Order of cost	Note
FPGA board with the right I/O	\$200–\$3,000	Choose by the interface you must prove , not by logic capacity. A board without the connector is useless however large its fabric
Vendor toolchain	\$0 (free tier) – \$3,000	The free tier covers small and mid parts; check your part is in it before buying the board
Logic analyser, on-chip	\$0 — bundled	The single most valuable debug tool ; budget the block RAM it eats
USB protocol analyser / scope	\$300–\$5,000	Only if the interface is external and slow enough to see
High-speed scope or BERT	\$20,000+ or rented	Rent by the day, or use the far end's own error counters

Item	Order of cost	Note
Partner hardware to interoperate with	varies	Often the largest real cost and the highest value
Bench supplies, cables, adapters	\$200–\$800	Underestimated

Ranges, not quotations. The point is the shape: the board and the partner hardware matter and the instruments mostly do not, because modern high-speed links carry their own error counters and a rented instrument answers the rest.

Worked example 58. What the prototype has to demonstrate, in order

Given. Part Y7's bring-up sequence, applied to an IP block on an FPGA.

Method. Each step is a claim you will make to a customer. Do them in dependency order and stop at the first that fails.

1. Bitstream loads, clock runs	the board and the build
2. ID register reads the right constant	power, clock, reset, bus, decode — all in one read
3. Scratch register writes and reads back	the write path
4. Internal loopback passes traffic	the datapath, no external risk
5. One external transaction	debuggable; the channel now included
6. Line-rate traffic for an hour	buffering, back pressure, rate matching
7. Overnight with error counters read	the number you quote
8. Against a second vendor's part	interoperability — the claim worth the most

How this is got wrong. By starting at step 6. Running traffic before the ID register reads is how a week disappears: every failure has a dozen candidate causes and none of the cheap tests has been done. Part Y7's information argument applies exactly — each early step splits the hypothesis space evenly and costs minutes, and skipping them does not save the minutes, it spends days.

27.3 Instrumenting for a bench you will be alone at

Table 409. What to build into the RTL before the board arrives

Feature	Cost	What it saves
ID register with a known constant	a dozen gates	Six hypotheses in one read
Scratch register	32 flops	Separates the write path from the function
Internal loopback	a multiplexer	Splits 'inside the chip' from 'outside' — the one clean partition
Per-stage error counters, saturating	a counter each	Tells you <i>which</i> stage, not just that something failed
Snapshot register on first error	a register set and a sticky bit	The first failure is the debuggable one; the thousandth is not
State register readable	wires	A stuck state machine names itself
Pattern generator and checker	a small LFSR pair	Removes the host from the loop — tests at line rate with no software
On-chip logic analyser trigger outputs	a few wires	Lets the bundled analyser trigger on your condition, not on time

Graduate · **All eight are cheap, and all eight must exist before the board arrives.** Adding instrumentation during bring-up means a rebuild, and a rebuild on a large FPGA is an hour you spend staring at a progress bar while the failure is still unexplained. The habit worth forming is to write the debug features in the same sitting as the datapath they observe, when you still remember what could go wrong with it. **They are also a sales feature:** a customer bringing your block up in their chip has exactly the same problem you did, and a block that names its own failures is materially cheaper for them to integrate — which is the argument Part Y5 makes about support cost, arriving as concrete RTL.

Problem. You have no partner hardware and no budget for it. Can you still claim interoperability?

Solution. No, and saying so is better than the alternatives. What you *can* claim, precisely, is conformance: ‘passes the standard’s test vectors’, ‘matches the reference implementation bit for bit on n random cases’, ‘runs at line rate against an open-source implementation of the far end’. That last one is the most useful and the most overlooked — for most protocols in this book an open implementation exists, and running against it is a genuine second implementation even though it is not a product. **Then say what is untested and what it would take.** A customer who reads ‘interoperability not yet demonstrated; we have run against X and the gap is a plugfest’ can decide whether to lend you hardware, which happens more often than a first-time vendor expects, or to treat it as a risk they price. **A customer who reads an interoperability claim that turns out to mean ‘against ourselves’ stops reading the rest of the datasheet.**

Z8. The Money

Part Y5 covers licensing structures. This part is narrower and more uncomfortable: what a one-person house's first three years look like as numbers, where the money actually goes, and which of the failure modes are arithmetic rather than bad luck.

Z8.1 The cost base

Table 410. Where the money goes in year one

Item	Order of cost	Note
Your living cost	\$40k–\$120k / yr	The dominant term. Everything else is noise beside it
Standards membership and documents	\$0–\$50k / yr	Zero for open standards, five figures for some bodies — and this is a gate, not a preference (Part Z5)
EDA tools	\$0–\$50k / yr	\$0 is viable for soft IP (Part Y14); the line appears only if you must sign off
Compute	\$0–\$3k / yr	Genuinely small. The agent runs on one machine overnight
FPGA bench	\$500–\$5k one-off	Part Z7
Legal (contract templates, one review)	\$2k–\$10k one-off	Do not skip the indemnity review — Part Y5
Accounting, insurance, entity	\$1k–\$5k / yr	Jurisdiction dependent
Conferences and plugfests	\$2k–\$10k / yr	The highest-return line per dollar for a house nobody has heard of

Ranges, not quotations — they vary by country, body and year, and this repository has not obtained current price lists. The shape is what transfers: your time is the cost base and almost everything else is optional or small, with the two exceptions in bold.

Graduate · Read the tools line against the standards line. The received wisdom is that EDA licences are what keep individuals out of chip design. For *soft IP* that is no longer true — Part Y14 measures a complete model-to-synthesis flow at zero — and the barrier has moved to a less discussed place: **the specification**. A protocol block you cannot legally read the standard for cannot be built at any price, and some bodies' membership is a five-figure annual commitment before a line of RTL exists. **That is the real gate, and it is why Part Z5 weights 'specification obtainable' at 3** and why the post-quantum candidate scores so well: NIST published everything.

Z8.2 Three years, three scenarios

Table 411. Three years at a \$120k/yr cost base, revenue in thousands

Path	Year 1	Year 2	Year 3	Cumulative	Verdict
서비스만 (계약 검증·모델링)	90	130	150	10	생존
서비스 + 블록 하나	70	140	200	50	생존
블록만, 고객 없이 시작	0	80	240	-40	못 버틴다
블록 가족 (둘째가 싸다)	60	200	340	240	아슬

Illustrative numbers, computed from the stated assumptions — not a forecast and not anyone's actual results. The purpose is the ranking, which is robust to changing the inputs: the row that starts with no revenue is the row that does not survive, and it is the row most first-time houses choose because it is the most technically satisfying.

Worked example 59. How long the runway has to be

Given. You have savings S , a cost base of \$120k/yr, and the first licence revenue lands in month M .

Method. Compute the required savings for several values of M , and note what determines M .

Cost per month	10,000 USD
First revenue at month 12	120,000 USD needed
At month 18	180,000 USD
At month 24	240,000 USD
Part Y8's block takes	39 weeks $\approx$ 9 months to build
Then evaluation, negotiation, integration	3–9 months more before money moves
So realistic M without services	18–24
With services from month 1	M does not matter

How this is got wrong. By budgeting the build and not the sale. The nine months are the part you control and the least of it; a customer's evaluation, legal review and purchase cycle is measured in quarters and does not start until the block exists. **That gap is why Part Y8 recommends services first**, and the recommendation is not about risk appetite — it is that the alternative requires two years of savings, and the failure mode is running out three weeks before the first sale, at which point the asset is worth nothing to you.

28.3 Pricing the first block

Table 412. Four ways to set the first price, and what each signals

Approach	Number	What the customer reads
Cost plus margin	Part Y5's arithmetic	Nothing — they cannot see your cost
Fraction of their alternative	What it would cost them to build it	The only argument that lands. Their engineer-year is the comparison
Market comparable	What incumbents charge	Credible if you can name the comparables; weak if you cannot
Below cost for a reference	Low, explicitly one-off	Rational once , and only with a written reference commitment in exchange

Do not discount to win the first deal without getting something back for it. The discount is defensible — a first customer takes a real risk on an unproven supplier and a public reference is worth more to you than the margin. What is not defensible is giving it away quietly: the price becomes the anchor for every subsequent negotiation, the customer's procurement remembers it, and you have bought nothing. **Trade it explicitly:** a named reference, a quotable result, an introduction, or a commitment to the second block in the family at full price. Write the exchange into the contract, because a verbal promise of a reference does not survive a change of contact.

Problem. A customer asks for source code escrow, unlimited indemnity, and a five-year support commitment. Which do you agree to?

Solution. Escrow: yes, and budget the annual fee. It is a reasonable request from anyone betting a product on a one-person supplier, and refusing it confirms exactly the risk they are worried about. Keep the deposit current — a stale escrow is worse than none, because it creates false comfort. **Unlimited indemnity: no,** and this is the one to hold. Cap it at fees received, which is standard and which a competent counterparty will accept; uncapped IP indemnity can exceed the value of everything you own, and no price compensates for that because the loss is unbounded. If they will not move, the deal is not worth doing at any price. **Five-year support: yes, with the scope defined.** Define what an update is — bug fixes in the delivered version, yes; a new revision of the standard, no, that is a new product — define a response time you can actually meet alone including holidays, and price the years beyond the first separately. **The general rule is that the ones to resist are the unbounded ones,** not the expensive ones; expensive is a number you can put in the quote, unbounded is not.

Z9. Scaling the Agent to a Block That Is Actually Big

The blocks this book's agent verifies are small — tens to hundreds of lines. A sellable block is thousands. This part is about what changes, because several things that work at the small scale stop working, and knowing which ones in advance is the difference between a method and a demonstration.

Z9.1 What breaks as the block grows

Table 413. Each mechanism at both scales

Mechanism	At 30 lines	At 3000 lines	Holds?	What replaces it
Regression runtime	0.03 s	minutes	Fine — it runs at night	Use Verilator for the bulk run; keep Icarus for X-propagation
Mutation pass	15 s	hours to days	Breaks — mutants × seeds × runtime is a triple product	Sample the mutants; run the full set weekly
Repair search	8 candidates	thousands	Breaks — and most edits are irrelevant to the failure	Restrict candidates to the cone of the failing output
Minimal reproducer	one stimulus line	a sequence	Breaks — shrinking a sequence is a different algorithm	Delta-debugging over the transaction sequence
Golden model runtime	micro-seconds	comparable to the RTL	Can break	Model in C++ and link it, or compare at checkpoints
Stimulus generation	random in a loop	constrained, layered	Breaks — random reaches nothing interesting	Constraint solving, sequences, and directed corners
Distinct-output check	trivially satisfied	still trivially satisfied	Holds — but becomes weak	Replace with functional coverage bins

Three of seven break, and they break for the same reason: the work is a product of several quantities that each grow with the design. The replacements are all standard verification practice — the agent's structure does not change, only the components inside it.

Worked example 60. When the mutation pass stops fitting in a night

Given. Mutants scale roughly with lines; each mutant is run on k seeds; each run takes time proportional to the design.

Method. Compute the triple product at three sizes and find where twelve hours runs out.

30 lines: mutants × seeds × run	$8 \times 1 \times 0.03 \text{ s} = 0.24 \text{ s}$
300 lines	$80 \times 2 \times 0.3 \text{ s} = 48 \text{ s}$
3000 lines	$800 \times 2 \times 3 \text{ s} = 1.333 \text{ h}$
30 000 lines	$8000 \times 2 \times 30 \text{ s} = 133.3 \text{ h}$
Hours available per night	12
Where it stops fitting	around 3000–10 000 lines
The fix	sample mutants nightly, full set weekly
Sampling 10 % nightly at 30k lines	13.33 h

How this is got wrong. By treating the mutation score as something run once at release. Sampled nightly it is a *trend*, and the trend is what detects Part Z6's first failure mode — the oracle standing still while the design grows. A single number at release cannot detect that, and by then it is too late to act on it anyway.

29.2 Shrinking a sequence, not a value

Delta debugging, and why it is worth implementing

	Step	Justification
1	A sequential failure is a <i>sequence</i> of transactions, not one input.	<i>So the current shrink — replay the one failing stimulus — does not apply.</i>
2	Naive minimisation removes one transaction at a time and re-runs: $O(n^2)$ runs for length n .	<i>At $n = 10\,000$ and one second a run, that is weeks.</i>
3	Delta debugging halves instead: try the first half, then the second, then quarters, keeping any subset that still fails.	<i>$O(n \log n)$ in the worst case and far better in practice, because failures usually depend on a few transactions.</i>
4	The result is a <i>1-minimal</i> sequence: removing any single transaction makes it pass.	<i>Which is usually two or three transactions out of ten thousand, and that is a debuggable report.</i>
5	It needs only a predicate: does this sequence still fail?	<i>Which the harness already provides. That is why it is cheap to add — the expensive part, the oracle, already exists.</i>

Table 414. Shrinking a failing sequence: one-at-a-time against delta debugging

Transactions	Naive runs	Delta-debug runs (bound)	Speed-up	Delta-debug time
100	10,000	1,328	7.526	0.3691 h at 1 s/run
1,000	1,000,000	19,931	50.17	5.537 h at 1 s/run
10,000	100,000,000	265,754	376.3	73.82 h at 1 s/run
100,000	10,000,000,000	3,321,928	3010	922.8 h at 1 s/run

Worst-case bounds; in practice delta debugging does far better because it finds the small dependent subset early. The naive column is why nobody shrinks long sequences by hand, and the third column is why the agent should.

29.3 Constrained stimulus: where random stops working

Table 415. Stimulus layers, and what each reaches

Layer	Reaches	Cost	When you need it
Uniform random	The bulk of the state space	free	Always — the first 90 % of coverage (Part X8)
Weighted random	Rare values, boundaries	A distribution per field	As soon as any field has a rare-but-legal value
Constrained random	Only legal combinations	A solver	When illegal stimulus wastes the night
Sequences	Protocol states that need a history	A sequence library	The moment the block has state — which is immediately
Directed corners	What random never reaches	One test each; you write them	Part X8's argument: some bins have probability 10^{-9}
Replay of past failures	Everything previously found	Almost nothing — keep the minimal reproducers	Every night. This is the cheapest coverage in existence

Graduate · **The last row is the one to build first, and it is routinely skipped.** Every failure the agent has ever found, reduced to its minimal reproducer, is a test that costs nothing to re-run and that is known to have caught a real bug once. A growing file of them is a regression suite assembled for free from work already done, and it is the only part of the stimulus that is guaranteed to be relevant to *this* design rather than to a designer's idea of it. **This repository's agent writes the minimal reproducer into its ledger; turning that ledger into a replay set is a few lines and should be the first thing added when a block gets big.**

Problem. At what size should you stop using one agent and split the block?

Solution. The question is better posed as: at what size does the *oracle* stop being a single comparison? The agent's structure is indifferent to size; what fails is the golden model's granularity. While one model consumes the block's inputs and produces its outputs, one comparison suffices however large the block is. **The break comes when a failure's distance from its cause becomes too large** — an error injected in a pipeline's first stage that manifests as a wrong packet ten thousand cycles later, where the minimal reproducer is still ten thousand transactions and the repair search has no cone to restrict to. At that point split the *comparison*, not the block: add internal checkpoints where the model and the RTL can be compared — after the syndrome stage, after the key equation, after Chien — each with its own small oracle. **This is step-and-compare from Part X19 applied to a datapath**, and it converts one hard debugging problem into several easy ones. The cost is that the internal interfaces become part of the verification contract and cannot be changed freely, which is a real constraint and is usually worth it.

Z10. The RS-KP4 Decoder, Planned Block by Block

Part Y15 states where this project stands. This part is the plan that would finish it: each sub-block, what its golden model is, how the agent verifies it, what its gate looks like, and how long it takes. It is written so that it can be executed rather than admired.

Z10.1 The decomposition

Table 416. Sub-blocks, each with its own oracle and its own gate

Sub-block	What it is	Golden model	State	Effort	Note
Syndrome	30 accumulators, 64 symbols/cycle	<code>rs.신드롬()</code>	Exists as a one-step block ; widen it	3 weeks	Dominates area — Part Y15's count
Key equation (BM)	Serial, $2t$ iterations	<code>rs._BM()</code>	New	4 weeks	Small area, fixed latency
Chien search	Evaluate σ at 544 positions, 64/cycle	<code>rs._치엔()</code>	New	3 weeks	Second-largest block
Forney	Magnitudes from σ and ω	<code>rs._포니()</code>	New	2 weeks	Needs a field inverse — table or Itoh–Tsujii
Delay FIFO	One codeword in flight	trivial	New	1 week	5,440 bits — the block's main memory
Re-check after correction	Recompute syndromes on the corrected word	<code>rs.복호()</code> does this	New	1 week	Turns silent miscorrection into a flag — Part X5
Top level, AXI-Stream	Handshake, packet boundaries, back pressure	the Python decoder end to end	New	3 weeks	Part X37's rules

Every golden model already exists, in this repository's `rs.py`, verified by 13 tests including mutation guards. That is the unusual part of this plan and the reason it is credible: the hardest thing to get right is already done and already checked.

Graduate · **Total 17 weeks of RTL, against Part Y8's 39-week plan for a sellable block.** The difference is everything downstream: the verification environment, the release gate, the documentation, the packaging, the synthesis and timing runs, and the buffer. **The RTL is about a third**, which matches Part Y1's effort table for MIPI and is the ratio a first-time vendor most consistently gets wrong.

Z10.2 How each sub-block is verified, concretely

Each sub-block becomes an agent block in exactly the form Part Z1 describes: a DUT file, a testbench, and a `block.py` whose `자극()` drives it and whose golden values come from `rs.py`. The pattern is already demonstrated by `blocks/rs_syndrome`.

Table 417. The verification plan per sub-block

Sub-block	Stimulus that must be in the set	Why
Syn-drome	Zero errors; 1 error; exactly $t=15$; $t+1$; all-zero codeword; all-ones	Zero errors must not pass as success — <code>rs.측정()</code> refuses to report a pass from a zero-error trial
Key equation	Every error count $0 \dots t+2$; degenerate syndromes	The iteration count is data independent, so the corners are about degree, not timing

Sub-block	Stimulus that must be in the set	Why
Chien	Roots at position 0, at 543, adjacent roots, repeated roots	Repeated roots mean the locator is wrong — the decoder must flag, not correct
Forney	Error magnitudes at the field's extremes; a zero denominator	Part X5's decoder returns failure on a zero denominator; the RTL must too
Top level	Back-to-back codewords with no gap; a stall in the middle of a codeword; reset mid-codeword	Part X37 and Part X42 — the integration failures

Worked example 61. What the agent can check that a human review cannot

Given. RS(544,514) over GF(2¹⁰), $t=15$. The decoder must correct every pattern of up to 15 symbol errors and must not silently miscorrect beyond.

Method. Count the patterns. Then note which of the two properties is checkable by sampling and which is not.

Error positions of weight 15	$C(544,15) \approx 10^{29}$
Magnitudes per position	1,023
Total patterns	astronomically many
What sampling establishes	a bound on the failure rate, not correctness
What the algebra guarantees	all patterns of weight $\leq t$, by the code's minimum distance
So the RTL must be checked against	the model, not the space
And the model against	the algebra — which tests/test_rs.py does by property, not by sample

How this is got wrong. By trying to verify the RTL directly against the specification's guarantee. The guarantee is over a space nobody can enumerate; what is checkable is agreement with a model whose own correctness rests on properties that *are* checkable. **This two-level structure is why the golden model must be verified by properties rather than by vectors** — and it is exactly what this repository's test_rs.py does when it breaks the syndrome computation and asserts the measurement notices.

Z10.3 The three unconfirmed constants, and the plan around them

Table 418. What is not known, and what it blocks

Unknown	Fixed by	Blocks	Work that proceeds anyway
Field polynomial	IEEE 802.3 Clause 91	Interoperability — not correctness	Everything. It is a parameter; the RTL takes it as one
First consecutive root fcr	Same clause	Interoperability	Same — a parameter
Symbol bit order	Same clause	The byte/symbol packing at the boundary	The core; only the top-level packer depends on it

Parameterising is not a substitute for reading the clause, and the plan should not pretend otherwise. A parameterised decoder is correct for whatever parameters it is given and interoperable with nothing until the parameters are right. What parameterising buys is that *the unknown stays visible* — a hard-coded constant dissolves into an assumption nobody ques-

tions, and Part Y15's scorecard would quietly lose its most important row. **The first item in the plan remains: obtain the document.** Everything else is work that can proceed in parallel, and none of it is work that can substitute.

Problem. Sixteen weeks of RTL and the specification is still unobtainable. Do you build it anyway?

Solution. Build the parts that are parameter-independent and stop before the parts that are not, and be explicit with yourself about which is which. The field arithmetic, the Berlekamp–Massey iteration, the Chien search structure and the Forney computation are all *generic* — they are correct for any primitive polynomial and any first root, and building them is not speculative. The top-level packing, the interoperability claim and the datasheet are parameter-dependent and should not be written. **What you must not do is pick a plausible value and proceed as though it were confirmed**, because that converts a known unknown into an unknown one, and the failure surfaces at a plugfest in front of the people you most want to impress. **The strategic answer, though, is to reconsider the product.** Part Z5's scorecard weights specification availability at 3 precisely so that this situation is visible before sixteen weeks are spent, and its winner — a post-quantum core whose standard, reference implementation and test vectors are all public — exists because that row was weighted honestly. A block you cannot obtain the specification for is not a cheaper project; it is a different one.

Z11. Writing the AXI Wrapper a Customer Will Accept

Almost every block a design house sells is bought as an AXI peripheral, and almost every integration complaint is about the wrapper rather than the core. This part is the wrapper — what it must do, what it must not do, and the specific mistakes that cost a week at the customer's end.

The core knows nothing about AXI. The wrapper knows nothing about the algorithm.
That separation is what lets you sell the same core with three different wrappers.

Figure 52. The separation that makes a core sellable more than once.

Z11.1 Keep the protocol out of the core

Why the boundary pays for itself three times

	Step	Justification
1	A core that consumes and produces values, with a simple ready/valid or an enable, has no protocol in it.	<i>It can be tested against the golden model directly — Part Z1's arrangement.</i>
2	The wrapper translates AXI into that.	<i>And it is the same wrapper for every core you build.</i>
3	First payment: verification. The core is verified against the model; the wrapper is verified against the protocol.	<i>Two small problems instead of one large one, and the protocol half is reusable.</i>
4	Second payment: the customer. Some want AXI-Stream, some AXI4, some a bare FIFO, some APB for configuration only.	<i>A core with the protocol baked in has to be re-written for each.</i>
5	Third payment: the standard changes and the core does not.	<i>AMBA revisions, a move to CHI, a customer's proprietary fabric — all wrapper work.</i>
6	The cost is one extra level of hierarchy and a handful of registers.	<i>Which Part X37's skid-buffer argument says you wanted anyway, because registering the boundary is what keeps your timing independent of their floor-plan.</i>

Table 419. What belongs on each side of the line

Belongs in the wrapper	Belongs in the core
AXI channels and their handshakes	The algorithm
Burst handling, ID management, ordering	Word lengths and pipelining
The register file (generated — Part Z4)	Nothing about registers — it takes parameters and strobes
Clock domain crossing, if the customer's is different	One clock; no assumptions about its rate
Error responses (SLVERR, DECERR)	An error <i>flag</i> , not a bus code
Back pressure and buffering	A stall input it honours — nothing more
Low-power and isolation (Part X43)	A clock enable

Z11.2 The wrapper mistakes that cost a week

Table 420. Eight wrapper defects, what each looks like, and the fix

Mistake	Symptom	Fix
s_ready depends combinationally on s_valid	Deadlock or oscillation when the partner does the same	Register one side; a skid buffer costs two entries and one cycle
No skid buffer, both directions registered	Throughput halves and functional tests still pass	Part X37's table — measure transfers per cycle, not correctness
Read and write share an internal queue	Deadlock in the customer's system, never in yours	Part X11 — keep the AXI channels independent all the way in
Bursts allowed to cross a 4 kB boundary	Protocol violation the interconnect may not check	Split in the wrapper; it is a comparison and an adder
WSTRB ignored	Neighbouring bytes corrupted on a narrow write	Honour it, or declare the register file 32-bit-only in the guide
Write response returned before the write is visible	A driver's read-after-write returns stale data	Define and document the visibility point
Reset not synchronised per domain	One boot in a thousand (Part X42)	Two flops per domain; the constraint shipped with the block
Register map hand-written into the wrapper	Diverges from the header and the data-sheet	Generate it — Part Z4

Six of the eight pass a functional test. They are found at integration, at line rate, or in the customer's system — which is why the release gate of Part Z3 checks throughput and why the testbench must apply randomised back pressure rather than accepting everything.

Worked example 62. Proving the wrapper does not halve your throughput

Given. An AXI-Stream wrapper around a core that accepts one word per cycle. The customer will measure sustained throughput with back pressure applied at random.

Method. State the bound, measure it, and put the measurement in the datasheet — the same three steps the agent's throughput check performs.

Ideal	1 word/cycle
With random back pressure at 50 %	0.5 word/cycle — expected
With a missing skid buffer	0.25 — and every value is still correct
What a value-only regression says	pass
What the throughput check says	cycles > bound → red
Where the bound comes from	measured on the clean block over several seeds
This repository's example	crc32_stream: 2.18 clean vs 3.16 broken cycles/byte, bound 2.6

How this is got wrong. By declaring a bound from the architecture rather than from a measurement. The architectural ideal is one word per cycle and no real testbench achieves it, so a bound set from the ideal never fires and a bound set by guessing is either useless or a false alarm. **Measure the clean block on several seeds, check the spread is small, and set the bound just above it** — which in this repository's case caught a mutation that a value-only suite had missed.

Z11.3 What ships with the wrapper

Table 421. The wrapper's own deliverables

Item	Why the customer needs it
The SDC constraints for the boundary	Your timing claim is meaningless without them — Part X14
CDC constraints, if the block crosses domains	Their tool will flag the crossing and stop; the waiver must come from you
Protocol assertions (SVA) on the AXI interfaces	They can bind them in their environment and see your block behaving
A bus functional model or a trivial testbench	So they can run it in ten minutes, which is when they decide
The register map in IP-XACT	Automated integration
A reference integration: your block plus a stub master	Removes the whole class of 'it does not work' reports where the wiring was wrong

Graduate · **The reference integration is the item with the best return and the one most often left out.** It is an hour's work: your block, a minimal master that writes the registers and streams some data, and a script that runs it. What it removes is the first two days of every customer's evaluation, during which they are wiring your block up for the first time and every problem looks like your problem. **A customer who runs your reference in ten minutes and sees traffic move has formed an opinion about your competence before reading the datasheet**, and that opinion is expensive to change later in either direction.

Problem. The customer's interconnect is CHI, not AXI. How much work is that?

Solution. Ask first whether it has to be, because the answer is often no. Most CHI systems provide AXI bridges for peripherals, and a block that does not need coherence has no reason to speak CHI — so the first move is to establish whether the block is a coherent agent or a device behind a bridge, and for a datapath accelerator it is almost always the latter. **If it genuinely must be a coherent agent**, the work is substantial and is *not* a wrapper change: CHI is a coherence protocol with a snoop interface, ordering rules and a state machine, and Part X28's verification argument applies — the state space is the kind that needs formal methods, and the effort is comparable to the core itself. **For a one-person house that is a reason to decline or to scope it as a separate project**, not a line item in a wrapper quote. The middle case worth naming: some blocks need only IO-coherence, where the block's accesses snoop the host caches but nothing snoops the block. **That is an interconnect feature, not a block feature**, and it costs you nothing — which is worth knowing so you do not quote for work the customer's fabric already does.

Z12. Writing the Documents

Documentation is where a one-person house is at its biggest disadvantage and, unusually, where it can be at its best: a document written by the person who made the decisions is better than one written by a technical writer three months later. This part is the structure, the rules, and what this repository's own documents look like.

Z12.1 Three documents, three readers

Table 422. Who reads each one, and what they are deciding

Document	Reader	The decision they are making	Fails when
Datasheet	An evaluator, before buying	Does this block do what we need, at the rate we need?	Numbers without conditions; claims without evidence
Integration guide	An engineer, after buying	How do I wire this in without calling them?	It documents the block and not the <i>integration</i>
Known issues	Both	Can I trust this supplier?	It is absent, or it says 'none'

Graduate · The known-issue list is read as a character reference and should be written as one. An evaluator has seen datasheets before and knows every block has limitations; what varies is whether the supplier says so. A list with eight dated entries, each with impact, workaround and status, says that someone has thought about the failure modes and is willing to be held to them. An absent list says either that nobody looked or that somebody decided not to tell you, and the evaluator cannot tell which — so they assume the worse one. **This is the cheapest credibility available to a supplier nobody has heard of,** and it costs an afternoon.

Z12.2 The rules that make the numbers usable

Table 423. Six rules, each with the version that fails it

Rule	Good	Bad	Why
Every number carries its conditions	'2.18 cycles/byte, random back pressure, seeds 1/7/99'	'1 byte per cycle'	A number without conditions cannot be reproduced or disputed
Name the tool, the library and the version	'208 cells, yosys 0.33, open library'	'~2 kGE'	Part Y14 — the honest smaller claim beats the unattributed larger one
Say what was not measured	'Area in your process: not measured. Scripts included'	Silence	Silence is read as a claim
Separate measured from derived	'measured 2.18; bound set at 2.6'	'2.6 cycles/byte'	A bound and a measurement are different facts
Give the reproduction command	bash edu/house/release.sh crc32_stream	—	This is what turns claims into evidence
Date everything	'2026-09-19, v1.0'	undated	An undated known-issue list is a list of excuses

All six are about the reader's ability to check you, which is the only thing that distinguishes a datasheet from marketing. A vendor who makes checking easy is making a bet that the numbers hold, and evaluators read that bet correctly.

Table 424. This repository's own documents, counted at build time

File	Reader	Lines	Table cells	Measured-value mentions	Links to the issue list
DATASHEET.md	evaluator	72	100	3	yes

File	Reader	Lines	Table cells	Measured-value mentions	Links to the issue list
INTEGRATION.md	integrator	62	0	0	—
KNOWN_ISSUES.md	both	27	80	0	yes

Counted by reading the files as this page rendered. The measured-value column is the one to watch: a datasheet whose count is zero is a list of intentions.

Z12.3 The datasheet, section by section

Table 425. What each section must answer

Section	The question	The commonest omission
1. What it is	Does this solve my problem?	Naming the standard but not the profile or the options
2. Interface	Can I connect it?	The handshake rules — which side may depend on which
3. Performance	Is it fast enough?	The conditions the number was measured under
4. Area and frequency	Does it fit?	Either silence, or an FPGA number presented as an ASIC one
5. Verification	Can I trust it?	Evidence that the tests bite — the mutation score
6. Configuration	Can I tune it?	Parameters listed without their legal ranges or their interactions
7. Known issues	What will bite me?	The whole section
8. Deliverables	What do I get?	Whether the testbench and scripts are included

Worked example 63. How long the documents take if written weekly

Given. A 39-week block. Documentation written at the end, versus twenty minutes at the end of each week.

Method. Compare the totals, and then the quality, which is the part that does not appear in the total.

Written at the end	1–2 weeks solid
Written weekly	13 hours total
Ratio	about 3× cheaper
And the quality difference	weekly notes record <i>why</i>; end-of-project notes record <i>what</i>
What is lost by waiting	the reason a constant has its value, the corner that forced a structure, the thing that nearly went wrong
Who needs the why	the customer's integrator, and you in a year

How this is got wrong. By treating documentation as transcription. It is not — it is the record of decisions, and decisions are only recoverable while they are fresh. The three-times cost difference is real and is the smaller of the two effects; the larger one is that a document written at the end cannot contain the information that makes it worth reading. **Part Z2 puts this in the Friday slot for exactly this reason**, and it is the slot that disappears first.

Problem. Your block has 40 configuration parameters. How do you document them without writing 40 pages?

Solution. Generate the list and write prose only about the interactions, because the list is mechanical and the interactions are not. **Generated:** name, type, legal range, default, and what it affects — from the same source that produces the RTL parameters, exactly as Part Z4's register map is generated. That is a table nobody writes and nobody can get out of sync. **Written by hand:** the three or four *combinations* that matter — which parameters must move together, which ones are ignored when another is set, which ones change the area or the latency and by roughly how much. **And a short list of the two or three configurations you have actually verified and synthesised**, named, with their numbers. That last item is the honest core of it: 40 independent parameters is 2^{40} configurations and you have verified a handful, so say which handful and state the covering argument for the rest (Part X19's pairwise criterion is the standard one). **A customer choosing an unverified combination should know that is what they are doing**, and a supplier who tells them is worth more than one who implies all 2^{40} were tested.

Z13. Week One

This book is long and the first Monday is short. This part is what to do in the first five days if the aim is a two-member team producing sellable IP, in an order that leaves something working at the end of each one. Everything it names exists in this repository and can be copied.

Z13.1 The five days

Table 426. Week one

Day	Goal	What you do	Why this and not something else
Monday	Get the flow running	Install iverilog, verilator, yosys, Python. Clone this repository. Run <code>bash edu/house/release.sh gf_mul</code> and watch it pass.	You now have a working gate on somebody else's block , which is the fastest way to see what one looks like
Tuesday	Make it your block	Copy <code>edu/agent/blocks/gf_mul</code> . Replace the RTL with the smallest thing you actually want to build. Write <code>block.py</code> 's <code>자극()</code> against a golden model you did not write.	The golden model must be independent — a library, a reference implementation, the standard's vectors
Wednesday	Make the checks bite	Run <code>mutscore.py</code> . Read every escape. Fix the stimulus until the score is above 90 % with every remaining escape judged in writing.	This is the day that teaches the most , and it is the day this repository's register file went from 58 % to 100 % and surfaced two real bugs
Thursday	Declare a bound	Measure the clean block's cycles over several seeds. Declare <code>성능한계()</code> just above the spread. Break the block so it is only slower and confirm the gate catches it.	A value-only suite cannot see a block getting slower
Friday	Write the three documents and run the gate	Datasheet, integration guide, known issues — short, with the numbers you measured this week and their conditions. Then <code>release.sh</code> and read what it says.	It will say you cannot sell it yet, and it will say exactly why

No architecture, no algorithm, no big block. The week builds the apparatus; the apparatus is what makes every later week cheap. A week spent the other way round produces a nicer block and no way to know whether it works.

The instinct is to start with the interesting block. It is the reason to be doing this at all, and it is the wrong first week: a large block with no gate is a large block you cannot make claims about, and the gate is far easier to build against something trivial. **The 30-line GF multiplier in this repository exists for exactly that reason** — it is small enough that every part of the apparatus can be seen working, and the apparatus transfers unchanged to a block a hundred times larger.

Z13.2 What each day leaves behind

Table 427. The artefacts, and what each proves

After	You have	You can say
Monday	A green gate on a known-good block	'my flow works' — which you could not say before
Tuesday	Your RTL compared against an independent model	'it agrees with X on n cases'
Wednesday	A mutation score with judged escapes	'the suite catches k % of injected defects, and here are the ones it does not and why'
Thursday	A measured throughput bound that fires	'it sustains x , and the gate proves it has not regressed'

After	You have	You can say
Friday	Three documents and a gate report	'here is what is done, here is what is not'

Worked example 64. What the first week costs and what it saves

Given. Five days building apparatus instead of five days building the block.

Method. Count what the apparatus does over the following months, using this book's own measurements.

Cost	5 days
Nightly regression thereafter	free
Bugs the mutation score surfaced here in one afternoon	2
Where those bugs would otherwise have been found	the customer's driver
Cost of a bug found by a customer (Part X8)	$10^3-10^4 \times$ a specification-stage fix
Break-even	the first real bug
Additional return	every block after this one starts on Tuesday

How this is got wrong. By counting the week as lost time. It is the only week whose output is reusable without modification across every block the house will ever build, and the ratio in the fifth row means it pays for itself the first time the gate catches something. **The honest caution is that it does not *feel* like progress**, which is why it is worth deciding in advance to spend it.

Z13.3 Where to go next in this book

Table 428. Reading order after week one

If you are	Read	Because
Choosing what to build	Part Z5, then Part Y6	Scorecard first, then the prior-art discipline that stops you rebuilding something
Writing the golden model	Parts X1 and Y11	Fixed point is most of the work and independence is the whole point
Choosing an architecture	Parts X2, X6, X13	Timing budget, memory-versus-arithmetic, the roofline
Stuck on verification	Parts X8, X33, Z6	Coverage arithmetic, where formal helps, what the agent cannot do
Getting it to close timing	Parts X2, X14, X34	The budget, the physical consequences, what synthesis can and cannot fix
Preparing to sell	Parts Z3, Z4, Y5, Z12	The bar, the pack, the commercial terms, the documents
Talking to a customer	Parts Y5, Y9, Z8	Scoping, compliance, money
Scaling past a toy	Part Z9	What breaks and what replaces it

Problem. You have read this book and you have a day job. Is any of this possible part-time?

Solution. The apparatus is, and the block is not — and separating the two is the useful answer rather than a discouraging one. **The apparatus is compatible with part-time work** because the agent runs when you are not there: an hour in the evening spent strengthening the oracle is repaid by a night of unattended checking, which is the one part of this arrangement that does not scale with your hours. Week one is five evenings rather than five days. **What is not compatible is the customer side:** evaluations, plugfests, support response times and the conversations of Part Z5 all happen during business hours and cannot be deferred, and Part Z8's arithmetic says the customer side is what decides whether the business exists. **So the honest part-time plan is to build the apparatus and one small, complete, publishable block** — which is a portfolio (Part Y13) and an asset and a genuine thing to point at — and to treat the transition to selling as a separate decision that needs the day job to end. **Conflating the two is how people spend two years part-time and arrive with neither.**

Z14. The C++ Model Layer — One Source, Two Destinations

Ask a working design house where its models live and you rarely hear “SystemVerilog.” You hear C or C++. The RTL is what you sell; the C++ is what tells you the RTL is right, and increasingly it is also what *generates* the RTL. This part builds that layer for real. Every file named here is in this repository, compiles with g++, and is exercised while this page renders.

Z14.1 Why the model is C++ and not Python

Earlier parts of this book used Python golden models (zlib for CRC-32, gf.py for the Galois field). That was right for those blocks: the model existed already, independently, which is the property that makes a golden model worth having. It stops being right the moment the model has to do two jobs:

Table 429. What the model layer has to do, and what language can do it

Job	Python	C++	Why
Be the verification reference	yes	yes	Both express the algorithm exactly.
Run billions of vectors	no	yes	Measured below: 144 M evaluations/s in C++. CPython is ~1000× slower.
Be the HLS input	no	yes	Every HLS tool in industry takes C, C++ or SystemC. None takes Python.
Be bit-accurate to the RTL	awkward	yes	Python ints are arbitrary precision. Overflow and truncation must be simulated by hand; in C++ the fixed-width types do it.

The third row is the one that changes the architecture of the whole flow. If the model is also the HLS input, then the model and the RTL *cannot disagree*, because there is only one description:

One source, two destinations

The conventional flow has three descriptions — a Python model, a C++ HLS source and hand-written RTL — and therefore three chances to disagree. When they disagree, nobody knows which is right, because each was written from the spec by a different person on a different day. The structure above removes two of the three.

Z14.2 The shared header, and why it has no vendor types

edu/model/ipmodel.h declares the fixed-point contract. It deliberately uses `int32_t` and hand-written saturation rather than `ap_fixed` or `hls::stream`. That was not a style choice; it was measured. Part Z15 gives the four one-variable controls that forced it.

```
// C++ 에서 음수 우시프트는 C++20 이전에는 구현정의지만, gcc·clang 은
// 산술 시프트로 하고 Bambu 도 같다 -- 그래도 기대는 것이 싫어서
// **나눗셈으로 적지 않는다**: 나눗셈은 0 쪽으로 자르고 시프트는 -무한 쪽으로
// 자른다. 둘이 음수에서 다르다. RTL 은 시프트를 하므로 모델도 시프트다.
static inline int32_t asr(int32_t v, int n) {
    return (v < 0) ? ~(~v >> n) : (v >> n);    // 부호와 무관하게 floor 시프트
}

// n비트 부호있는 범위로 포화. 자르지(wrap) 않고 **포화**하는 이유:
// 링크 등화기에서 wrap 은 큰 양수를 큰 음수로 뒤집어 슬라이서를 정반대로
// 틀리게 만든다. 포화는 틀려도 같은 부호 쪽으로 틀린다.
static inline int32_t sat(int32_t v, int n) {
    const int32_t hi = (int32_t)((1u << (n - 1)) - 1);
    const int32_t lo = -hi - 1;
    return v > hi ? hi : (v < lo ? lo : v);
}

// 아래 n비트만 남긴다 (부호 없음). RTL 의 `[n-1:0]` 과 같다.
static inline uint32_t mask(uint32_t v, int n) {
    return n >= 32 ? v : (v & ((1u << n) - 1));
}
```

Two details in that code are worth the ink, because both are places where a model and an RTL silently part company.

Why the shift is written as a shift and not a division

	Step	Justification
1	The RTL computes <code>acc[16:7]</code> — an arithmetic right shift by 7.	<i>That is what the hardware does; a shift is free, a divider is not.</i>
2	In C, <code>acc / 128</code> rounds toward zero. <code>acc >> 7</code> rounds toward negative infinity.	<i>Integer division truncates toward zero by definition (C99 6.5.5); a shift discards low bits, which floors.</i>
3	For <code>acc = -1</code> : division gives 0, shift gives <code>-1</code> .	<i>$-1/128 = -0.0078$ truncates to 0; $-1 >> 7 = -1$.</i>
4	So writing the model with division makes it disagree with the RTL on every negative value whose magnitude is below the shift amount.	<i>That is roughly half of all small negative accumulator values — common in an equaliser sitting near zero.</i>
5	Therefore <code>asr()</code> is written as a shift, with the sign handled explicitly so it does not rely on implementation-defined behaviour.	<i>C++ left negative right-shift implementation-defined until C++20.</i>

The second is saturation versus wrapping. A wrap turns a large positive accumulator into a large negative one, which drives the slicer to exactly the wrong decision; a saturate is still wrong but wrong in the same direction. The model saturates because

the RTL saturates, and the RTL saturates because the specification says so. All three have to agree or the comparison is theatre.

Z14.3 Proving three architectures equal — by exhaustion

`fir.h` contains the same filter written three ways: the textbook form, a width-narrowed form, and a symmetry-folded form that uses two multipliers instead of four. They have to compute the same function. Most projects establish that by running a few thousand random vectors and declaring victory. Here the input space is four 8-bit samples, so it has exactly 4,294,967,296 points — and that is small enough to check *all of them*.

Table 430. Exhaustive equivalence, measured

Quantity	Value	What it means
Input space	4,294,967,296	256^4 — every possible input
Wall time	29.7 s	g++ -O2, one core
Rate	144,419,484/s	Each point evaluates all three variants
Disagreements	0	Not “none found” — none exist
Distinct outputs	256	All 256 output codes occur, so the check is not degenerate

That last row is the gate this repository puts on every measurement. A comparison that only ever sees one output value has proved nothing, however many vectors it ran. `equiv.cpp` counts distinct outputs and exits non-zero if there are fewer than two — the same rule the RTL harness applies in Part Z1.

The word “proof” is used carefully. This is exhaustive over the *stated* input space, which is the combinational function of four samples. It says nothing about the sequential wrapper, the reset behaviour, or the handshake. Those need different arguments — and in Part Z15 one of them costs us a bug.

Z14.4 What verification time actually looks like

“C++ simulates a thousand times faster than RTL” is repeated everywhere and is almost never measured by the person repeating it. Measuring it on this design produces a more useful answer than the folklore.

Table 431. Vectors per second, same algorithm, same machine

Path	Vectors/s	Relative	What is included
C++, compute only	144,419,484	1,616×	The arithmetic, nothing else (<code>equiv.cpp</code>)
C++, formatted to a file	5,110,455	57×	Same arithmetic plus <code>printf</code> of five integers
RTL, iverilog + vvp	89,345	1×	Event-driven simulation of the synthesisable design

Worked example 65. Where the speed advantage goes

Given. C++ computes at 144,419,484/s but emits formatted vectors at only 5,110,455/s.

Method. Divide. The ratio is the cost of text formatting relative to the algorithm itself. 28×. Formatting five integers as decimal text costs about 28 times more than computing the filter output. The practical rule: a C++ reference that talks to the RTL through a text file throws away almost all of its speed advantage. Use the file for the few thousand vectors the RTL will actually run, and keep the billion-vector sweeps entirely inside C++.

How this is got wrong. The obvious reading is “file I/O is slow.” It was measured and it is not: writing 200,000 vectors to a file ran at 5,110,455/s and discarding them to `/dev/null` ran at 5,398,353/s — a 5 % difference. The cost is `printf`'s decimal conversion, not the disk. Replacing text with a binary buffer, or comparing in memory and never serialising at all, recovers the other 96 %.

So the honest version of the folklore is: the algorithm is about 1,600× faster in C++, and a badly plumbed harness will give you 57×. Both are worth having; they buy different things. The 57× path is how you drive the RTL. The 1,600× path is how you settle the algorithm before any RTL exists — and that is where the schedule is actually won, because a bug found in the C++ costs minutes and the same bug found in a gate-level regression costs days.

Z14.5 Order of work, and what it saves

Table 432. Where each class of defect should die

Defect class	Cheapest place to catch it	Cost if it escapes to RTL
Algorithm wrong (wrong formula, wrong rounding)	C++, exhaustive or bulk	Days — the RTL is right and the spec is wrong, which is the slowest kind of debug
Overflow / width	C++ with fixed-width types	Weeks — appears as “fails occasionally”
Handshake, reset, backpressure	RTL only	Cannot be found in C++; budget RTL time for exactly this
Timing / area	Synthesis and P&R only	Cannot be found in simulation at all

The two lower rows are why HLS does not remove the need for RTL verification. It removes the top two rows, which are most of the defects by count, and leaves the bottom two, which are most of the defects by *difficulty*. Part Z15 hits one of the third-row defects within ten minutes of first running the generated RTL.

Z15. HLS — What It Costs, and How to Make It Win

High-level synthesis has two well-known drawbacks. The first is that it does not always compile what you give it. The second is quality of results: the generated RTL can use noticeably more of the device than RTL a person would have written. Both are real, and both are measured in this part on a filter that exists in this repository.

But “generated RTL is worse than hand RTL” is not a law. It is what happens when the C++ is written as if it were software. If you understand the specification, the architecture you actually want, and what the HLS tool does with what you wrote, the generated RTL can beat hand-written RTL — and below it does, by 1.38× in clock frequency. The rest of this part is how.

Z15.1 Drawback one: what the tool refuses

Before any quality question there is a compile question. These are one-variable controls run against PandA Bambu 2024.10 in this container: each row changes exactly one thing from the row above, so the cause is not inferred.

Table 433. What Bambu accepts and refuses — one-variable controls

Control	What changed	Result
1	Pure C, 8-tap FIR	rc=0, Verilog produced, 101.0 MHz
2	Control 1 plus one line : <code>#pragma HLS PIPELINE II=1</code>	rc=11 — Loop pipelining pragma not supported
3	C++ templates, no pragmas	rc=0, Verilog produced
4a	<code>ap_uint</code> only	rc=0, Verilog, 119–147 MHz
4b	<code>hls::stream</code> only	rc=1 — crash in <code>FixStructsPassedByValue</code>
5	<code>ap_fixed</code> complex 8×8 Cholesky	rc=124 — 40-minute timeout in the front end

Control 2 is the important one: the same file, one line added, a hard failure. The blocker is not C++ and not the algorithm — it is the *pragma dialect*. Every vendor has its own, and pragmas are exactly the part of an HLS source that does not port. Control 4a is the pleasant surprise: Xilinx’s arbitrary-precision integer type compiles fine on a tool that has nothing to do with Xilinx, because it is ordinary C++ templates. Control 4b is the unpleasant one, and it has no workaround.

The design rule that falls out of this table, and the one `edu/model/ipmodel.h` follows: **put the algorithm in portable C++ and keep every tool-specific thing out of it**. No pragmas in the header, no vendor stream types, no heavy template arithmetic. Then the same header compiles under g++ as the golden model and under the HLS tool as the design, and retargeting to a different HLS tool is a build-script change rather than a rewrite.

Z15.2 Drawback two: quality of results, measured

The filter is four taps, 8-bit samples, constant symmetric coefficients. Written naturally in C++ — `int` parameters, `int` accumulator, the way anybody would write it — and handed to Bambu, it produces this:

Table 434. The same algorithm, the same tool, only the C types differ

HLS source	Port width	Cells	SB_LUT4	SB_CARRY
<code>int fir_top(int,int,int,int)</code>	32 bit	1,218	890	199
<code>signed char fir_top_tuned(signed char×4)</code>	8 bit	338	228	97

Worked example 66. Where a 4-tap filter's 890 LUTs came from

Given. A 4-tap FIR with constant coefficients needs, by hand, about 200 LUT4 on this device. The naive HLS version used 890.

Method. Compare the two rows above. The algorithm is identical — the same header, the same arithmetic, verified bit-identical. Only the C parameter types differ.

3.60× reduction (1,218 cells to 338) from changing `int` to `signed char` in the function signature. Nothing else changed. This is the single largest QoR lever in HLS and it costs one line. It is also the first thing to check when generated RTL comes back four times too big.

How this is got wrong. The tempting explanation is “HLS tools are bloated.” It is not that. C's integer promotion rules widen `char` and `short` operands to `int` before arithmetic, so a C++ source that says `int` is *requesting* a 32-bit datapath and 32-bit ports. The tool built what the source asked for. A person writing Verilog types `[7:0]` and cannot make this mistake — which is most of why naive HLS loses to hand RTL.

Z15.3 Making the comparison honest

Three things had to be fixed before any number in the next table meant anything. Each of them, left unfixed, produces a confident and wrong result.

Table 435. Three ways this comparison was wrong before it was right

Problem	Symptom	Fix
The two designs computed different functions	None — area numbers looked fine and meant nothing	Verify both against the same C++ golden vectors first. Every design in the next table passes 400 vectors with 0 mismatches.
Reset polarity differed	The generated RTL never asserted done; 400/400 “failed”	Bambu defaults to active-low reset; the hand RTL used active-high. <code>--reset-level=high --reset-type=sync</code> .
Frequency was measured on the wrong path	Adding pipeline registers made Fmax <i>fall</i> (324 MHz → 74 MHz), and the hand RTL reported no frequency at all	<code>nextpnr</code> reports register-to-register paths only. Wrap every design in an identical registered timing shell (<code>fir_shell.v</code>) so the path being measured is the datapath.

The third deserves emphasis because it is the kind of error that survives review. The numbers before the fix were not noise — they were stable across seeds and they were monotonic in the wrong direction. A stable, reproducible, completely meaningless measurement is the most dangerous kind, because every instinct says to trust it. What made it visible was not a tool warning; it was noticing that *more registers cannot make a design slower*, and refusing to write the number down until that contradiction was explained.

Z15.4 The sweep — where HLS loses and where it wins

Table 436. Area, frequency and latency — all verified against the same C++ golden model (0 mismatches in 400 vectors each)

Design	LC	Fmax (MHz)	Latency (cyc)	Fmax vs hand pipe	Area vs hand pipe
Hand combinational	252	47.2	1	0.61×	0.98×
Hand 3-stage pipeline	256	76.9	3	1.00×	1.00×
HLS @ 10ns	299	57.2	2	0.74×	1.17×
HLS @ 6ns	307	72.7	4	0.95×	1.20×
HLS @ 3ns	386	105.9	9	1.38×	1.51×

Design	LC	Fmax (MHz)	Latency (cyc)	Fmax vs hand pipe	Area vs hand pipe
HLS @ 2ns	460	92.3	12	1.20×	1.80×
HLS @ 1ns	544	82.6	18	1.08×	2.12×

Frequency is the mean of three placer seeds; the spread was under 7 % on every row, so the differences below are larger than the noise. Device is iCE40 HX8K, nextpnr-ice40 --freq 300 --placer heap.

Worked example 67. Does the generated RTL beat the hand-written RTL?

Given. Hand-written 3-stage pipeline: 256 LC at 76.9 MHz, latency 3. Best HLS point (HLS clock=3ns): 386 LC at 105.9 MHz, latency 9.

Method. Compare each axis separately. There is no single QoR number; area, frequency and latency trade against each other. Frequency: 1.38× **better**. Area: 1.51× worse. Latency: 3.0× worse. So the answer is: yes on frequency, no on area and latency, and only at one point in the sweep. Anyone quoting the 1.38× without the 1.51× area and 3× latency is selling, not measuring.

How this is got wrong. Two trivial explanations had to be killed. First, that the hand RTL was a straw man: the comparison is against a hand-written *pipelined* design, not the single-cycle one, precisely so the answer is not rigged. Second, that tightening the constraint always helps: it does not. At 2 ns and 1 ns the generated design is both **larger and slower** than at 3 ns. The knee is at 3 ns and you only find it by sweeping.

Z15.5 The method — how to get better QoR than hand RTL

The 1.38× did not come from the tool being clever. It came from four things, in this order. Each is a thing you do, not a thing the tool does.

Why the generated RTL could win at all

	Step	Justification
1	Write the interface at the true width, not the C default.	<i>Measured above: 3.60× area from this alone. Until this is done, nothing else matters — the design is four times too big and every later measurement is taken on the wrong design.</i>
2	Express the architecture you want, not just the arithmetic you want.	<i>The folded form computes $h_0(x_0+x_3)+h_1(x_1+x_2)$: two multipliers instead of four. The tool will not discover the symmetry; you state it, and <code>equiv.cpp</code> proves you stated it correctly.</i>
3	Let the tool re-schedule, and sweep the constraint.	<i>One number, <code>--clock-period</code>, produced five different microarchitectures with latencies 2, 4, 9, 12 and 18 cycles. In hand RTL each of those is a re-design; here each is a rebuild.</i>
4	Pick the knee from the sweep rather than the tightest point.	<i>The best frequency is at 3 ns, not at 1 ns. Constraining harder past the knee adds registers that the fabric cannot exploit, so area rises and frequency falls.</i>

Step three is where the structural advantage lives, and it is worth being precise about what it is. The tool is not out-scheduling a human. A human given a week could hand-pipeline this filter to 3 ns and would probably land smaller than 386 LC. The advantage is that the sweep above cost **four rebuilds and no design work**, so five architectures were evaluated instead of one. Hand RTL usually gets pipelined once, for one target, because re-pipelining is expensive and risky; it then stays that way when the target moves. The generated design is re-derived from the specification every time.

That is the real claim, and it is narrower and more useful than “HLS beats hand RTL.” **Hand RTL beats HLS at a point you have already designed for. HLS beats hand RTL at a point you have not.** In a one-person design house, where nobody has a week to re-pipeline a block because a customer moved the clock from 75 to 100 MHz, the second case is the one that keeps happening.

Z15.6 Where this result stops being true

Stating the conditions under which a measurement flips is not a disclaimer; it is part of the measurement. This one flips under any of these:

Table 437. Invalidation conditions for Z15.4

Condition	Why the result changes
A different fabric	iCE40 has no DSP blocks usable here, so constant multiplies became LUT shift-adds. On a device with hard multipliers the area picture changes completely.
Wider data or more taps	At 4 taps the hand design is small enough for one person to hold in mind. The argument for HLS gets <i>stronger</i> with size, but this table does not prove that — it was not measured here.
A hand design with more than 3 stages	The comparison is against a 3-stage hand pipeline. A 6-stage hand pipeline would likely beat the 3 ns HLS point on both axes. What it would cost in engineer-days is not in the table.
A different HLS tool	Bambu's scheduler is not Vitis HLS's. The pragma dialect result in Z15.1 guarantees the sources are not portable unchanged.

The last row is the one to plan around commercially. An IP built on one HLS tool's pragmas is tied to that tool. An IP built the way `edu/model/ipmodel.h` is built — portable C++, tool-specific settings on the command line — is not, and that portability is worth more than the few percent a vendor pragma might buy.

Z16. Before Any Code — System, Spec, Schematic

Everything so far in this volume started from a piece of RTL or a piece of C++. That is the wrong end. In a real design house the code is the *fifth* thing you produce, and by the time you type it most of the decisions that matter are already made. This part walks the four things that come first, for the same 4-tap equaliser the previous parts built: where it sits in a system, what it is responsible for, what its specification says, and what it looks like as a drawing — all the way down to transistors.

Nothing here assumes prior hardware knowledge. If you have written C++ and never seen a schematic, this part and the two after it are written for you.

Z16.1 What problem this IP exists to solve

A serial link sends bits down a copper trace. At 10 Gb/s a bit is 100 picoseconds wide, and a 30 cm PCB trace behaves like a low-pass filter: high frequencies are attenuated more than low ones. The consequence has a name — **inter-symbol interference** (ISI). Energy from bit n is still arriving when bit $n+1$ is being sampled, so the receiver's decision about one bit depends on the bits around it.

Figure 53. What the channel does. The transmitted waveform (top) is clean. The received waveform is smeared across bit boundaries — drawn as ‘unknown’ because at the sampling instant its value depends on neighbouring bits, not just the current one. Recovering the top row from the middle row is the equaliser's job.

An equaliser undoes that smearing. A **feed-forward equaliser** (FFE) does it with a filter whose response approximates the inverse of the channel: take the last few samples, scale each by a coefficient, add them up. That sum is the filter this book has been building. Four taps, 8-bit samples, coefficients $\{-18, 111, 111, -18\}$ in Q1.7 — a mild high-frequency boost, which is exactly the shape that undoes a mild low-pass channel.

Worked example 68. Why those coefficients have that shape

Given. The coefficients are $\{-18, 111, 111, -18\}$ in Q1.7, i.e. $\{-0.141, 0.867, 0.867, -0.141\}$.

Method. Sum them to get the DC (zero-frequency) gain. Alternate their signs and sum to get the Nyquist (highest-frequency) gain.

DC gain = $(-18+111+111-18)/128 = 186/128 = \mathbf{1.453}$. Nyquist gain = $(-18-111+111+18)/128 = 0/128 = \mathbf{\text{exactly zero}}$. The filter passes DC at $1.45\times$ and has a perfect null at the highest representable frequency. This is the difference between a teaching example and a product. The structure, widths, saturation, handshake and verification in this book are all real. The coefficient values are placeholders, and the book says so rather than letting the reader assume otherwise.

How this is got wrong. That is a **low-pass** response — and not a mild one: a null at Nyquist is what a smoothing filter does, the opposite of what an equaliser is supposed to do. The negative outer taps make it *look* like a boost, but the adjacent equal centre taps dominate and their sum $111-111$ cancels exactly at Nyquist. Treat this filter as what it is — a worked example with realistic structure, arithmetic and saturation behaviour — not as a coefficient set anyone should ship. Real FFE coefficients are adapted at run time by an LMS loop against the measured channel, and the sign pattern is typically the other way round.

Z16.2 Where it sits — the whole receive chain

The filter is one box in a chain. Knowing the boxes on either side is not background reading; it is what determines your interface, your latency budget and your clock.

Figure 54. The 10 Gb/s receive chain. Our IP is the fourth box. Everything before it is analogue or mixed-signal; everything after it is ordinary synchronous digital logic. The boundary sits at the ADC — which is exactly why the IP's input is an 8-bit two's-complement sample and not a voltage.

Table 438. Each neighbour, and what it forces on our design

Block	What it does	What it forces on us
CTLE	Continuous-time linear equaliser: an analogue filter that boosts high frequencies before sampling.	It removes the bulk of the ISI, so our digital FFE only has to clean up the residue — which is why 4 taps is enough and 40 is not needed.
VGA / AGC	Variable-gain amplifier with automatic gain control: scales the signal so it fills the ADC's input range.	It guarantees our input occupies most of the 8-bit range. If AGC is broken our input is tiny and the filter output is mostly quantisation noise — a failure that looks like our bug.
ADC	Analogue-to-digital converter: turns a voltage into an 8-bit number, once per unit interval.	Defines our input format. 8-bit, two's complement, Q1.7, one sample per clock. Everything about our widths comes from this box.
DFE	Decision-feedback equaliser: subtracts the known ISI contribution of already-decided bits. Contains a feedback loop.	It sits immediately after us and its loop must close in one unit interval. Our latency is in series with nothing critical, but our throughput must be one sample per clock or the DFE starves.
Slicer	A comparator: decides 0 or 1 from the equalised sample.	It consumes our 8-bit output and only really needs the sign plus a few bits of margin — which is why saturating (rather than wrapping) matters so much: a wrap flips the sign and the slicer decides exactly wrong.
CDR	Clock and data recovery: extracts the sampling clock from the data.	It provides our clock. Our design must be fully synchronous to it and must tolerate its reset sequencing.
PCS / MAC	Protocol layers: alignment, 64b/66b coding, FEC, framing, CRC.	Far enough away not to constrain us directly, but they set the overall latency budget the whole chain is measured against.

Z16.3 “Front end” and “back end” mean two different things

This trips up every newcomer, because the same two words name two unrelated axes and practitioners switch between them without warning.

Table 439. Two meanings of front-end / back-end

Axis	Front end	Back end	Where our IP is
Signal chain (where in the data path)	Analogue and mixed-signal: CTLE, VGA, ADC, CDR. Deals in volts and picoseconds.	Digital: PCS, MAC, bus, software. Deals in bits and packets.	First block of the digital back end — immediately after the ADC.
Design flow (where in the schedule)	RTL design, verification, synthesis-for-estimate. Produces a netlist. This is where this book lives.	Floorplan, place and route, clock tree, timing closure, DRC/LVS, GDSII tape-out.	Parts Z14–Z15 are flow front-end. <code>synth.sh</code> 's <code>nextpnr</code> step is the smallest possible taste of flow back-end.

So “our IP is in the back end” and “we are doing front-end work” are both true at once, and mean different things. When someone says it, ask which axis.

Z16.4 The specification, written before the code

A specification is not a description of what you built. It is the contract you write first, and then check what you built against. Here is the real one for this block. Every row is a number a customer can hold you to, and every row was measured in Parts Z14–Z15 — the spec came first and the measurements came back to fill it in.

Table 440. IP specification: 4-tap feed-forward equaliser

Item	Value	How it is verified
Function	$y[n] = \text{sat}_g((\sum h[i] \cdot x[n-i]) \gg 7)$	Exhaustive C++ equivalence over all 2^{32} inputs (Z14.3)
Input	4 × 8-bit signed, Q1.7, one sample per clock	Testbench drives all corner combinations plus random
Output	1 × 8-bit signed, Q1.7, saturating	Saturation exercised by corner vectors; all 256 output codes seen
Coefficients	Compile-time constants, symmetric	Symmetry asserted at build; folding verified bit-exact against unfolded
Throughput	1 sample/clock, no back-pressure	Cycle count checked in the harness, not just values
Latency	1 clock (combinational variant) / 3 clocks (pipelined)	Measured start-to-done in simulation
Clock	Single clock, synchronous, rising edge	Lint (no latches, no multiple drivers) plus synthesis
Reset	Synchronous, active high	Explicitly stated because the HLS tool defaults to active low — see Z15.3
Area	252 LC (hand) / 386 LC (HLS @3ns) on iCE40 HX8K	yosys + nextpnr, three placer seeds
$F_{\max}$	76.9 MHz (hand, 3-stage) / 106.0 MHz (HLS @3ns)	nextpnr with a registered timing shell
Deliverables	RTL, C++ model, testbench, vectors, synthesis script, data-sheet, integration guide, known issues	<code>edu/house/release.sh</code> gates all of them

Two rows are worth pausing on. The **reset polarity** row exists because getting it wrong cost a debugging session in Part Z15 — a specification that does not pin down polarity, edge and synchronicity has not specified the reset at all. And **throughput**

is a separate row from latency because a value-only regression cannot see a block getting slower; Part Z1 caught a mutant that broke throughput while keeping every output value correct.

Z16.5 What else you must own to ship this

A 4-tap filter is not a product. A customer who buys “an equaliser” expects a block they can drop into a chip, and that means a surprising amount of surrounding machinery. For a one-person design house the question is not whether you need these — you do — but which you write, which you take from an open collection, and which you decline to support.

Table 441. Supporting IP, and the one-person make/buy call

What	Why it is needed	Call
Register file / CSR block	Coefficients, bypass, status, ID. No customer accepts a block with no software interface.	Make. Generated from one description — <code>edu/house/regmap.py</code> emits RTL, C header, docs and IP-XACT from a single source.
APB or AXI-Lite bridge	How the CSRs are reached from the SoC.	Make (APB is ~100 lines and fully specified) or take an open one. AXI-Lite is bigger; buy or adapt.
Clock-domain crossing / FIFO	The CSR bus and the data path are usually on different clocks.	Buy or adopt. CDC is the single most common source of bugs that pass simulation and fail silicon. Do not hand-roll a synchroniser.
Reset synchroniser	An asynchronous reset release violates recovery/removal timing on every flop it reaches.	Make , from the standard two-flop pattern, and lint for it.
PLL / CDR	Provides the clock.	Decline. This is analogue IP. A one-person digital house does not build a CDR; you specify the clock you need and document it.
SerDes PHY	Serialiser, driver, receiver front end.	Decline. Same reason, larger.
DFT / scan insertion	Manufacturing test. Without it the chip cannot be screened.	Defer to the integrator , but write RTL that is scan-friendly: no gated clocks you invented, no latches, no async logic.
Lint and CDC rule decks	Customers run them and send you the report.	Make. <code>verilator --lint-only -Wall</code> is free and catches most of it; ship the clean report as a deliverable.
Documentation set	Datasheet, integration guide, known issues.	Make. This is the cheapest thing you can do to look like a real vendor, and the thing most one-person efforts skip.

The honest summary of that table: the filter is perhaps 15 % of the work of selling the filter. Parts Y and Z4 build the other 85 %.

Z16.6 The five levels of drawing

“Schematic” is not one thing. The same design is drawn at five levels of detail and each answers a different question. Knowing which level you are being shown is half of reading a drawing.

Table 442. Levels of representation, from system to silicon

Level	What a box is	What a line is	Question it answers	Where in this book
System	A whole function (ADC, MAC)	A stream of data	Does the architecture close?	Z16.2, above
Block / RTL	A module with ports	A named bus of bits	What are the interfaces and widths?	Z16.7

Level	What a box is	What a line is	Question it answers	Where in this book
Datapath	An adder, a multiplier, a register	A bundle of wires	Where does the critical path run?	Z17.4
Gate	A NAND, a flip-flop	One wire carrying one bit	How many gates deep is it?	Z17.3
Transistor	One MOSFET	One node	Why does a gate behave as it does?	Z17.1–Z17.2

Z16.7 Our IP at block level

This is the drawing that belongs at the top of the datasheet. Boxes are modules, lines are buses, and the widths are on the lines because a width mismatch is the most common integration failure there is.

Figure 55. The equaliser at block level. Reading left to right: samples enter and are held in a 4-deep shift register; symmetric pairs are added (9 bits, because adding two 8-bit numbers needs 9); each sum is multiplied by one constant coefficient (17 bits); the result is shifted right by 7 to return to Q1.7 and saturated back to 8 bits. Every width change on this diagram is a place where a bug can hide silently.

Why every width on that diagram is what it is

	Step	Justification
1	The input is 8 bits because the ADC produces 8 bits.	<i>The interface is set by the neighbour, not by us.</i>
2	The fold adders are 9 bits, not 8.	<i>Adding two n-bit signed numbers can need n+1 bits: 127+127 = 254, which does not fit in 8-bit signed. Truncating here would be wrong only for large inputs — a bug that passes random testing.</i>
3	The multiply result is 17 bits.	<i>9-bit operand times 8-bit coefficient gives up to 17 bits. The accumulator is declared 18 in the C++ model, and the maximum magnitude is 127×(18+111+111+18) = 32,766, which fits in 17 bits signed with room to spare — so the 18-bit saturation in the model never actually fires.</i>
4	The shift is by 7, not 8.	<i>Both sample and coefficient are Q1.7, so their product is Q2.14. Returning to Q1.7 means discarding 7 fractional bits.</i>
5	The output saturates to 8 bits rather than wrapping.	<i>The next block is a slicer that decides sign. A wrap turns a large positive into a large negative and the slicer decides exactly wrong; a saturate is wrong in magnitude but right in sign.</i>

That last derivation is the whole argument for drawing before coding. It took five steps and no Verilog, and it fixed every width in the design. Written the other way round — code first, widths discovered during debug — each of those five steps becomes a regression failure somebody has to chase.

Z17. From One Transistor to Our Datapath

This part builds the equaliser upward from a single transistor. Nothing is assumed. If you know that a computer is made of transistors and nothing more specific than that, start here; by the end you will be able to read the gate-level schematic of the adder inside the filter and say why it is shaped the way it is.

The reason this matters to someone writing RTL or HLS is not nostalgia. Every decision the previous parts made — why saturation costs more than truncation, why a 9-bit adder is not an 8-bit adder, why the critical path runs where it does, why you register a signal before it leaves the chip — is a fact about these drawings. You can write RTL without them and you will write slower RTL.

Z17.1 The switch

A MOSFET is a voltage-controlled switch with three terminals that matter: **gate**, **source** and **drain**. Current flows between source and drain when the gate says so. There are two flavours and they are opposites:

Table 443. The two switches

Type	Turns on when its gate is	Good at passing	Where it goes
NMOS	high (1)	a strong 0	between the output and ground
PMOS	low (0)	a strong 1	between the output and VDD

The third column is the one people skip and then get wrong. An NMOS can pull a node down to 0 V cleanly but cannot pull it all the way up to VDD — it stops roughly a threshold voltage short. A PMOS is the mirror image. So neither type alone can build a good logic gate, and *that* is why every static CMOS gate contains both: PMOS above to pull up, NMOS below to pull down. The circuit family is called **complementary** MOS for exactly this reason.

Z17.2 The inverter, and why CMOS won

Figure 56. The CMOS inverter: one PMOS pull-up, one NMOS pull-down, gates tied together. This is the smallest complete CMOS gate and the template for every other one. The red bar at the top is the supply (VDD); the striped symbol at the bottom is ground (0 V).

Why this circuit inverts, and why it costs no static power

	Step	Justification
1	Input A = 0. The PMOS gate sees 0, so the PMOS is on . The NMOS gate sees 0, so the NMOS is off .	<i>From the table above: PMOS turns on with a low gate, NMOS with a high gate.</i>
2	With only the PMOS on, the output node is connected to VDD and disconnected from ground. Y is pulled up to 1.	<i>The only conducting path from Y goes to the supply.</i>
3	Input A = 1. Now the PMOS is off and the NMOS is on, so Y is connected to ground and disconnected from VDD. Y is pulled down to 0.	<i>The mirror image of the previous step.</i>
4	In both steady states exactly one of the two devices conducts, so there is no path from VDD to ground .	<i>A path from supply to ground would be a short circuit drawing continuous current.</i>
5	Therefore a CMOS gate that is not switching draws (almost) no current.	<i>This is the property that let CMOS displace every earlier logic family. Power is consumed charging and discharging capacitance when the output changes, which is why dynamic power is proportional to activity and frequency.</i>
6	The word 'almost' is doing real work at modern nodes.	<i>Sub-threshold leakage and gate leakage mean an idle gate does draw a small current, and below roughly 28 nm leakage becomes a first-order design problem. Part X43 covers what is done about it.</i>

Z17.3 NAND: pull-up and pull-down are duals

Now the gate that everything is actually built from. The rule that generates every static CMOS gate is a single sentence: **build the pull-down network from NMOS so that it conducts exactly when the output should be 0, then build the pull-up network as its dual.**

A·B 가 둘 다 1 일 때만 아래 길이 이어져 Y=0
 하나라도 0 이면 위 길이 이어져 Y=1 -> Y = NOT(A AND B)
 풀업과 풀다운은 언제나 서로의 쌍대(dual)다 -- 직렬 <-> 병렬

Figure 57. A 2-input CMOS NAND. The two NMOS are in **series**: current only reaches ground when A and B are both 1, which is exactly when NAND's output should be 0. The two PMOS are in **parallel**: a path to VDD exists when A is 0 or B is 0. Series means AND; parallel means OR.

Table 444. Reading the NAND schematic as a truth table

A	B	Pull-down (series NMOS)	Pull-up (parallel PMOS)	Y
0	0	both off → open	both on → conducts	1
0	1	top off → open	left on → conducts	1
1	0	bottom off → open	right on → conducts	1
1	1	both on → conducts	both off → open	0

Why the pull-up is the dual of the pull-down, always

	Step	Justification
1	The output must be driven to exactly one value in every input combination.	<i>If neither network conducts the output floats (high-impedance, value undefined); if both conduct you have a short from VDD to ground.</i>
2	So the pull-up must conduct exactly when the pull-down does not — the two conditions are logical complements.	<i>That is what ‘exactly one’ means.</i>
3	The pull-down for NAND conducts when (A AND B).	<i>Series transistors both have to be on, and NMOS is on for a 1.</i>
4	Its complement is $\text{NOT}(A \text{ AND } B) = (\text{NOT } A) \text{ OR } (\text{NOT } B)$, by De Morgan's law.	<i>De Morgan converts a negated conjunction into a disjunction of negations.</i>
5	PMOS is on for a 0, so a PMOS whose gate is A implements (NOT A). An OR of two conditions is a parallel connection.	<i>Either path alone is enough to conduct.</i>
6	Hence: series NMOS below, parallel PMOS above. Swap series and parallel and you get NOR instead.	<i>NOR's pull-down is parallel (output 0 when A OR B) and its pull-up is series.</i>

Two consequences worth carrying into RTL. First, **NAND and NOR are the cheap gates** — four transistors each. AND and OR are *more* expensive, because CMOS naturally produces an inversion and a non-inverting gate is a NAND followed by an inverter: six transistors. This is why synthesis tools cheerfully rewrite your logic into seas of NANDs, and why the classic identity $\text{AND}(a,b) = \text{NOT}(\text{NAND}(a,b))$ is worth recognising in a netlist.

Second, **series transistors are slow**. A 4-input NAND has four NMOS in series and its pull-down is roughly four times weaker than an inverter's. That is why wide gates get decomposed into trees, and why a 17-bit ripple adder is not simply ‘a bit slower’ than an 8-bit one.

Z17.4 Pull-up resistors — a different thing with a similar name

The phrase “pull-up” is used for two different circuits and conflating them causes real design errors.

Figure 58. Two things called “pull-up”. **Left:** a real resistor on a board, holding an open-drain line high until some device pulls it low. **Right:** a PMOS pull-up network inside a CMOS gate. Only the left one is a resistor; the right one is the transistor network of Z17.2.

Table 445. Resistor pull-up versus transistor pull-up

	Pull-up resistor (board level)	PMOS pull-up (inside a gate)
What it is	A physical resistor, typically 1–10 k Ω	A transistor network, the dual of the pull-down
Where	On the PCB or inside an I/O pad	Inside every static CMOS gate
Why	The line has no active driver for the high state — open-drain or open-collect-or outputs can only pull down	Every state is actively driven
Static current	Yes — whenever the line is held low, current flows through the resistor to ground	No — exactly one network conducts
Speed	Slow rising edge: RC charging of the bus capacitance. This is why I ² C is limited to 100 kHz/400 kHz/1 MHz modes	Fast: the PMOS actively charges the node
Typical use	I ² C SDA/SCL, shared interrupt lines, reset lines, strapping pins, unused inputs	All ordinary logic
Relevance to our IP	None inside the block. It appears at the chip boundary and in the CSR bus pads	Every gate the filter synthesises into

Worked example 69. Sizing a pull-up resistor, and why the choice is a squeeze

Given. An I²C bus at 3.3 V with 200 pF of bus capacitance. The standard requires the low level to stay below 0.4 V while a device sinks at most 3 mA, and the rise time to be under 300 ns for 400 kHz fast mode.

Method. The lower bound comes from current: R must be large enough that $(V_{DD} - V_{OL})/R$ does not exceed the sink current. The upper bound comes from speed: the RC rise to the input threshold must fit in the rise-time budget, which for $0 \rightarrow 0.7 V_{DD}$ takes about 1.2 RC.

Lower bound: $R \geq (3.3 - 0.4)/3 \text{ mA} = \mathbf{967 \Omega}$. Upper bound: $R \leq 300 \text{ ns}/(1.2 \times 200 \text{ pF}) = \mathbf{1250 \Omega}$. So R must sit between roughly 1.0 and 1.25 k Ω — a narrow window. Note what dominates: capacitance. Halving C doubles the upper bound. On a board, capacitance is trace length and the number of devices, so the electrical problem is really a layout problem.

How this is got wrong. The window being this narrow is the finding, not an arithmetic slip. The usual reflex is to grab the familiar 4.7 k Ω part, which violates the upper bound by nearly 4 $\times$ and produces a bus that works on the bench at low speed and fails at 400 kHz with long traces. If the window closes entirely, the fix is not a different resistor — it is less bus capacitance, or an active terminator.

Z17.5 The clock, and why anything is clocked at all

Combinational logic has no memory: outputs follow inputs after a delay. To build anything that accumulates, you need an element that *holds*. The universal one is the edge-triggered **D flip-flop**: it samples its D input at the rising edge of the clock and holds that value on Q until the next rising edge.

Figure 59. A D flip-flop. Q takes the value D had at the rising edge and holds it for the whole cycle. Note that Q changes only at rising edges, never in between — that is the entire point.

The clock is not there to make things go. It is there to make things *agree on when*. Combinational paths through different amounts of logic finish at different times; without a clock, a downstream block cannot know whether what it is looking at is the final answer or a value still settling. The clock defines an instant at which everything is required to have settled, and the design's job is to make that true.

Table 446. The two timing constraints, and what violating each looks like

Con-straint	What it requires	Fix if violated	Symptom
Setup	Data must arrive at the flop at least t_{su} before the edge. Limits the longest path.	Shorten the logic, add a pipeline stage, or slow the clock.	Works at low frequency, fails above some clock rate. Reproducible.
Hold	Data must remain stable at least t_h after the edge. Limits the shortest path.	Add delay (buffers). Slow-ing the clock does not help.	Fails at every frequency. Usually a silicon respin — which is why hold violations are feared more than setup.

That asymmetry is worth memorising: a setup failure is a performance bug, a hold failure is a functional bug. It is also why Part Z15's measurement needed a registered timing shell — a path that starts or ends outside the chip has no flop at one end, so neither constraint is defined and the tool has nothing to report.

Z17.6 Our adder, at gate level

Now put it together. The filter's first operation is $a0 = x0 + x3$ on 8-bit signed values producing 9 bits. An adder is built from full adders, and a full adder is built from the gates above.

Figure 60. One full adder: $sum = a \text{ XOR } b \text{ XOR } cin$, $cout = (a \text{ AND } b) \text{ OR } (cin \text{ AND } (a \text{ XOR } b))$. Five gates. The 9-bit fold adder in the filter is nine of these chained, with each cout feeding the next cin — a ripple-carry adder.

Worked example 70. Why the carry chain sets the critical path

Given. A ripple-carry adder of N bits. Each full adder's carry output takes about 2 gate delays (one AND, one OR) after its carry input is valid.

Method. The last bit's carry cannot be computed until every earlier carry has rippled through. Count gate delays along that chain.

Roughly $2N$ gate delays for N bits: **18** for the 9-bit fold adder, **34** for a 17-bit accumulator. The sum bits themselves add only one more XOR after their carry arrives. This is also why fast-adder architectures exist — carry-lookahead, carry-select, prefix adders — trading area for a logarithmic rather than linear carry depth. On an FPGA you usually get the vendor's carry chain and the question does not arise; in an ASIC the synthesiser picks from a library of adder architectures based on your timing constraint.

How this is got wrong. The tempting conclusion is that our filter's critical path is the adder. It is not, and assuming so sends you optimising the wrong thing. The measured designs in Z15 use iCE40's dedicated carry chain (SB_CARRY), which is far faster than generic gates — the hand design used 48 of them. On this fabric the multiply-by-constant shift-add network, not the ripple, dominates. **Count gates to understand the structure; measure the tool output to know the number.**

Z17.7 Why saturation costs more than wrapping

Part Z16 justified saturation on system grounds: a wrap flips the sign and the slicer decides exactly wrong. Here is what it costs, in gates.

Table 447. Truncate versus saturate, at gate level

Operation	What the hardware does	Cost
Truncate (wrap) to 8 bits	Discard the upper bits. Route 8 wires, ignore the rest.	Zero gates. It is a renaming of wires.
Saturate to 8 bits	Detect whether the value exceeds the 8-bit range, and if so substitute the limit. Needs two comparisons and an 8-bit 2-to-1 multiplexer.	Two comparators plus a mux — tens of gates, and it sits after the adder, so it adds directly to the critical path.

This explains a result in Part Z15 that looked backwards at first. Narrowing the accumulator from 32 bits to 18 *should* have shrunk the design, but the narrowed variant came out larger in Bambu's estimate — because the narrowing was implemented with `sat()` at every accumulation step, and each of those saturations bought comparators that the plain 32-bit accumulation did not need. The width saving was real and the saturation cost was larger.

The lesson generalises: **narrowing a datapath is only free if you narrow it somewhere the value provably cannot overflow.** In the final tuned design the accumulator is wide enough that no intermediate saturation is needed at all — Z16.7 derived the bound, 32,766, which fits in 17 bits — and saturation happens exactly once, at the output, where the specification demands it.

Z17.8 The whole stack, one page

Table 448. Every level, and what our filter looks like there

Level	Our filter at this level	Who works here
System	One box in the receive chain, between ADC and DFE	Architect; the spec of Z16.4 is written here
RTL / HLS	40 lines of Verilog, or 12 lines of C++ plus a build command	You, in Parts Z14–Z15
Netlist	338–1218 cells depending on how the C++ was typed	Synthesis (yosys); you read its report

Level	Our filter at this level	Who works here
Gate	SB_LUT4 ×228, SB_CARRY ×97 — NANDs and carry chains in a specific arrangement	The tool; you influence it through coding style and constraints
Transistor	Each LUT4 is a small memory plus a mux tree; each is CMOS pull-up/pull-down as in Z17.2	The FPGA vendor, or in an ASIC the standard-cell library team
Silicon	Configuration bits in an iCE40, or diffused transistors in a mask set	The foundry

The practical point of having walked down this stack is that the levels are not independent. A choice at the top — “saturate rather than wrap” — became comparators and a mux at the gate level, which became area and delay in the measurements of Part Z15, which fed back into the specification in Z16.4. An engineer who can only see one level cannot follow that chain, and will make the choice at the top without knowing what it costs at the bottom.

Z18. SystemVerilog for the C++ Programmer

SystemVerilog looks enough like C to be dangerous. The braces are begin/end, the types are unfamiliar, and about a third of the constructs mean something that has no software equivalent at all. This part is a complete tour, written for somebody who knows C++ and has never seen a hardware description language. It covers the synthesisable language in full, then the verification subset, and says at every point which of the two you are in.

The single most important idea, before any syntax: **you are not writing instructions that execute. You are describing hardware that exists.** Every always block in a design is a piece of circuitry that is powered on all the time, simultaneously with every other block. Sequence exists only inside a single block, and even there it is often a fiction the synthesiser unrolls into wires.

Z18.1 The thing you asked about: ::

:: is the scope resolution operator, and it means very nearly what it means in C++ — “this name, from inside that namespace.” SystemVerilog has three scopes that use it.

Table 449. The three things that appear to the left of ::

Form	What the left side is	C++ analogue
my_pkg::WIDTH	A package — a named bundle of types, constants and functions shared across files.	namespace my_pkg { }, and this is the same syntax
state_e::IDLE	An enum type , naming one of its members explicitly.	enum class state_e { IDLE } — also the same syntax
std::mailbox	The built-in package, which holds mailbox, semaphore, process.	std::, and even the same name
\$unit::foo	The compilation unit scope — everything declared outside any package or module.	The global namespace, ::foo

```
// — 패키지: C++ 의 namespace 와 같은 자리다
package fir_pkg;
    // parameter = 컴파일 시간 상수. C++ 의 `constexpr` 에 해당한다.
    parameter int NTAP = 4;
    parameter int SAMP_W = 8;

    // typedef: C 와 똑같다. `logic signed [7:0]` 에 이름을 붙인다.
    typedef logic signed [SAMP_W-1:0] samp_t;

    // enum: C++11 의 `enum class` 처럼 타입이 붙는다.
    // 괄호 안 `logic [1:0]` 은 **이 enum 이 하드웨어에서 2비트로 인코딩된다**는
    // 뜻이다. C++ enum 의 underlying type 과 같은 개념인데, 여기서는
    // 실제 플립플롭 개수를 정한다.
    typedef enum logic [1:0] { IDLE, RUN, DONE } state_e;

    // 함수도 답을 수 있다. `automatic` 은 아래 Z18.9 에서 설명한다.
    function automatic int unsigned clog2_up(int unsigned v);
        clog2_up = 0;
        while (v > 1) begin v = v >> 1; clog2_up++; end
    endfunction
```

endpackage

```
// — 쓰는 쪽 —————
module fir_core;
    // (1) 매번 `fir_pkg::` 를 붙여 쓴다 -- C++ 의 `std::vector` 와 같다
    fir_pkg::samp_t a;
    localparam int N = fir_pkg::NTAP;

    // (2) enum 멤버를 타입 이름으로 한정한다
    fir_pkg::state_e st = fir_pkg::state_e::IDLE;

    // (3) import 로 통째로 끌어온다 -- C++ 의 `using namespace` 다
    import fir_pkg::*;
    samp_t b;                // 이제 접두사 없이 쓴다
endmodule
```

The difference from C++ that bites: **an import inside a module is visible only in that module**, and a package must be compiled *before* anything that imports it. There is no header-guard mechanism and no forward declaration; file order on the compiler command line is part of the build. Most projects keep one package per file and list packages first in the file list.

One more ::-adjacent thing that surprises C++ programmers: the dot. dut.internal_reg reaches *inside* another module instance from a testbench, past every encapsulation boundary. This is a **hierarchical reference**, it is legal, it is not synthesizable, and it is how most white-box testbenches are written. There is no private in SystemVerilog modules.

Z18.2 What a module is, and why it is not a class

```
// 모듈 = 하드웨어 한 덩어리. C++ 의 class 가 아니라 **회로 그 자체**다.
//
// class 와 다른 점:
// * 생성/소멸이 없다. 전원이 켜져 있는 동안 늘 존재한다
// * 메서드 호출이 없다. 포트에 신호가 들어오고 나갈 뿐이다
// * 인스턴스가 **컴파일 시간에 고정**된다. 런타임에 new 할 수 없다
// (verification 쪽 `class` 는 할 수 있다 -- Z18.11)
module fir4 #(
    // 파라미터 = 인스턴스마다 다르게 줄 수 있는 컴파일 시간 값.
    // C++ 의 **템플릿 인자**에 해당한다: `template<int SAMP_W>`
    parameter int SAMP_W = 8,
    parameter int NTAP    = 4
) (
    // 포트 목록. 방향이 반드시 붙는다.
    // input   읽기만 한다
    // output  이 모듈이 구동한다
    // inout   양방향 (삼상태). 칩 안에서는 거의 안 쓴다
    input logic                clk,
    input logic                rst,
    input logic signed [SAMP_W-1:0] x,
    output logic signed [SAMP_W-1:0] y
);
// ... 내용 ...
```

```
endmodule
```

```
// 인스턴스화.  `.포트이름(연결할신호)` 를 **이름으로** 잇는다.
// 순서로 잇는 옛 문법(`fir4 u(clk, rst, x, y)`도 되지만 **쓰지 마라** --
// 포트를 하나 추가하면 그 아래가 전부 조용히 밀린다.
fir4 #(.SAMP_W(8), .NTAP(4)) u_fir (
    .clk (clk_100m),
    .rst (rst_sync),
    .x   (adc_sample),
    .y   (eq_out)
);
```

Z18.3 Types: the four-state trap

C++ has `bool`. SystemVerilog has a bit that can hold four values, and the two extra ones are the most useful debugging tool in the language.

Table 450. The four values a logic bit can take

Value	Means	Where it comes from	Why you want it
0	low	driven low	—
1	high	driven high	—
x	unknown	uninitialised register, two drivers fighting, reading before reset	It propagates. An x in a sum makes the sum x, so a missing reset shows up as garbage rather than as a plausible zero.
z	high impedance (not driven)	a tri-state driver that is off, an unconnected input	Models buses where several drivers share a wire.

Table 451. The types, and which to use

Type	States	Use it for	C++ analogue
logic	4	Almost everything. One bit, or logic [7:0] for a vector.	Closest to <code>bool</code> / <code>uint8_t</code> , but 4-state
wire	4	Legacy. A net that must be continuously driven. <code>logic</code> covers it in SystemVerilog.	—
reg	4	Legacy Verilog name for a procedural variable. It does not mean ‘register’ — this misnaming has confused people for thirty years. Use <code>logic</code> .	—
bit	2	Testbench code where you want C semantics and speed.	<code>bool</code>
int	2	Loop counters, testbench arithmetic. 32-bit signed.	<code>int32_t</code>
byte, shortint, longint	2	8/16/64-bit signed testbench integers.	<code>int8_t</code> , <code>int16_t</code> , <code>int64_t</code>
integer	4	Legacy 32-bit 4-state.	—
real	—	Floating point, testbench only.	<code>double</code>
string	—	Testbench messages.	<code>std::string</code>

```
// — 벡터와 부호 —————
logic [7:0] u;    // 8비트 **부호 없음** (기본값)
```

```

logic signed [7:0] a;    // 8비트 부호 있음 -- `signed`를 빼면 조용히 틀린다

// [7:0] 과 [0:7] 은 다르다. [7:0] 이 관례다 (왼쪽이 MSB).
// C++ 배열과 달리 **비트 번호를 내가 정한다** -- [15:8] 도 legal 하다.

// 부호를 빠뜨리면 어떻게 되나 -- 실제로 물리는 자리다
logic      [7:0] p = 8'hFF;    // 255 로 읽힌다
logic signed [7:0] q = 8'hFF;    // -1 로 읽힌다
// p > 0 은 참, q > 0 은 거짓. **같은 비트, 다른 답.**

// — 리터럴 —————
// <폭>'<진법><값>
8'd10      // 8비트 십진 10
8'hFF      // 8비트 16진
8'b1010_1010 // 밑줄은 자리 구분용. 무시된다 (C++14 의 ' 와 같다)
8'sd10     // 8비트 **부호있는** 십진
'0         // 폭을 문맥에서 가져오는 전부-0. `1` 은 전부-1 (0001 아님!)
8'bx      // 전부 unknown -- 리셋 전 상태를 흉내낼 때

// — 구조체와 배열 —————
typedef struct packed {          // packed = **비트가 연속**이다. 합성된다
    logic      valid;           // [16]
    logic [7:0] data;           // [15:8]
    logic [7:0] tag;            // [7:0]
} beat_t;                       // 통째로 17비트 벡터처럼 쓸 수 있다

typedef struct {                 // unpacked = 그냥 묶음. **합성 안 된다**
    int count;
    string name;
} stat_t;                       // 테스트벤치용

logic [7:0] mem [0:255];        // unpacked 배열 = 메모리. `[개수]` 가 **뒤**에 온다
logic [3:0][7:0] lanes;        // packed 배열 = 32비트를 4x8 로 본 것
beat_t queue [$];              // 동적 큐 (테스트벤치). C++ 의 `std::deque`

```

Worked example 71. Why signed is the most expensive missing keyword in the language

Given. The filter adds two 8-bit samples: $a0 = x0 + x3$, where both may be negative. Written as `logic [7:0] x0` without `signed`.

Method. Work out what the comparison and the shift do under unsigned interpretation. $x0 = -1$ is stored as 8'hFF. Unsigned, that reads as **255**. Adding -1 and -1 should give -2 ; unsigned it gives 510, and the right shift that follows brings in zeros from the top instead of sign bits, so the result is a large positive number instead of a small negative one. The rule in SystemVerilog: an expression is unsigned if **any** operand is unsigned. One unsigned literal in a long signed expression silently converts the whole thing. When in doubt, wrap in `$signed()`.

How this is got wrong. Nothing warns you. The bit patterns are identical — only the *interpretation* differs, and the interpretation lives in a keyword you forgot to type. The design simulates, synthesises, and is wrong for exactly the half of the input space where the sample is negative. Random testing finds it; directed testing with positive-only stimulus does not. This is why `edu/model/fir4_hand.v` writes `$signed({x0[7], x0})` explicitly rather than relying on declarations being right.

Z18.4 The two assignments, and when to use which

This is the rule that separates working RTL from RTL that simulates and then fails in hardware. C++ has one assignment; SystemVerilog has two and they mean different things about *time*.

Table 452. Blocking versus non-blocking

	= blocking	<= non-blocking
Reads like	C's <code>=</code> : compute, store, move on.	"Sample all right-hand sides now; update all left-hand sides at the end of the time step."
Models	A wire — combinational logic.	A flip-flop — every register in the block updates together on the edge.
Use in	<code>always_comb</code>	<code>always_ff</code>
If you get it wrong	Non-blocking in combinational logic: simulates slowly and can need extra delta cycles, may mismatch synthesis.	Blocking in sequential logic: creates a race . Simulation result depends on the order the simulator happens to evaluate blocks in; hardware does something else.

```
// — 왜 순차 논리에 <= 를 쓰는가 —————
// 하드웨어에서 이 두 플립플롭은 **동시에** 잡힌다. a 가 b 로 가고 b 가
// c 로 가는 시프트 레지스터를 생각하면 된다.

always_ff @(posedge clk) begin
    b <= a;      // 이 edge 의 **옛** a 값을 잡는다
    c <= b;      // 이 edge 의 **옛** b 값을 잡는다
end

// 결과: 시프트 레지스터. a -> b -> c, 한 edge 에 한 칸. **맞다.**

always_ff @(posedge clk) begin
    b = a;       // b 가 **즉시** a 가 된다
    c = b;       // 그래서 c 도 **같은 edge 에** a 가 되어 버린다
end

// 결과: b 와 c 가 둘 다 a. 시프트 레지스터가 아니라 그냥 팬아웃이다.
// 더 나쁜 것: 다른 always 블록이 b 를 읽고 있으면, 그 블록이 이 블록보다
// 먼저 도느냐 나중에 도느냐에 따라 **옛 b 를 보거나 새 b 를 본다.**
```

// 시뮬레이터가 순서를 정하고, 그 순서는 명세에 없다 -- 그것이 경주다.

```
// — 조합 논리에는 = 를 쓴다 —————
always_comb begin
    sum = a + b;          // 중간값
    outv = sum + c;       // **방금 계산한** sum 을 쓴다 -- 그래서 blocking
end
// <= 로 쓰면 outv 가 이번이 아니라 **다음** delta 의 sum 을 본다.
```

The rule, stated once and never broken: **non-blocking in a always_ff, blocking in a always_comb, never both in one block, and never assign the same signal from two blocks**. Every lint tool checks it. The generated RTL in Part Z15 obeys it because the HLS tool cannot make this mistake — which is one genuine, if unglamorous, advantage of generating RTL.

Z18.5 The always blocks

// — SystemVerilog 의 세 가지 (Verilog 의 `always` 를 갈라놓은 것) —

```
// 1. 조합 논리. 감도 목록을 **도구가 채운다** -- 빠뜨릴 수가 없다
always_comb begin
    y = a & b;
end
// 옛 Verilog: always @(a or b) <- b 를 빠뜨리면 래치가 생긴다.
// `always_comb` 는 그 사고를 문법으로 막는다. **항상 이것을 써라.**
```

```
// 2. 순차 논리. edge 를 적는다
always_ff @(posedge clk) begin          // 동기 리셋
    if (rst) q <= '0;
    else    q <= d;
end

always_ff @(posedge clk or negedge rst_n) begin // 비동기 리셋
    if (!rst_n) q <= '0;                // 리셋이 감도 목록에 **있어야** 한다
    else        q <= d;
end
```

```
// 3. 래치. **의도적으로** 래치를 만들 때만. ASIC 에서는 거의 금지다
always_latch begin
    if (en) q = d;
end
```

```
// — 래치가 사고로 생기는 자리 —————
always_comb begin
    if (sel) y = a;          // sel 이 0 일 때 y 를 안 정했다
end                          // -> y 가 **이전 값을 기억해야** 한다 -> 래치!
// 고치는 법 두 가지:
always_comb begin
    y = '0;                  // (a) 먼저 기본값을 준다
    if (sel) y = a;
```

```

end
always_comb begin
    if (sel) y = a;          // (b) 모든 갈래를 채운다
    else    y = '0;
end
// `always_comb` 를 쓰면 도구가 "latch inferred" 라고 **경고**해 준다.
// 옛 `always @(*)` 는 조용히 만든다.

```

Z18.6 Operators: what is the same and what is not

Table 453. Operators a C++ programmer will misread

Operator	Meaning	The C++ trap
& ^ ~	Bitwise, on vectors.	Same as C++.
&& !	Logical, on truth of the whole value.	Same as C++.
&a a ^ a	Reduction — unary. &a is AND of every bit of a; ^a is parity.	No C++ equivalent. ^data computing parity in one character is the single most useful operator in the language.
== !=	Equality; result is x if either operand has an x.	Can return unknown, not just true/false.
=== !==	Case equality — compares x and z literally, always gives 0 or 1.	Use in testbenches to ask ‘is this actually X?’. Not synthesizable.
>> <<	Logical shift — brings in zeros.	Same as C++ unsigned shift.
>>>	Arithmetic right shift — replicates the sign bit. Only if the operand is signed.	C++ >> on a signed int does this; SystemVerilog needs the third angle bracket and a signed operand.
{a, b}	Concatenation — glue bits together.	No C++ equivalent. {x[7], x} is 9-bit sign extension.
{4{a}}	Replication — four copies of a.	{8{x[7]}} is the idiomatic sign-extend.
a inside {1,2, [5:9]}	Set membership, ranges allowed.	Like a switch without fallthrough; also used in constraints.
?:	Conditional. Synthesises to a multiplexer.	Same as C++, but remember it is <i>hardware</i> — both sides are always computed.

```

// — 이 저장소의 실제 코드로 본 연산자 —————

// 부호 확장: 8비트를 9비트로. {x0[7], x0} 이 최상위 비트를 한 번 더 붙인다
wire signed [8:0] a0 = $signed({x0[7], x0}) + $signed({x3[7], x3});

// 왜 $signed() 로 또 감싸나?
// {} 연결의 결과는 **언제나 unsigned** 다 -- 안에 뭐가 들었든.
// 이것이 SystemVerilog 에서 가장 흔한 조용한 버그 중 하나다.

// 비트 뽑기와 자르기
acc[16:7]          // 고정 범위
acc[i +: 8]        // i 부터 위로 8비트. i 가 변수여도 된다
acc[i -: 8]        // i 부터 아래로 8비트
// `acc[i+7 : i]` 는 **불법**이다 (범위 양끝이 다 변수면 안 된다).
// +:/- : 가 그것을 푸는 문법이다.

```

```
// 리덕션으로 패리티 한 줄
wire parity = ^data;           // data 의 모든 비트를 XOR

// 전부 0 인지 검사 -- 세 가지가 다 같은 뜻이다
wire empty1 = (count == '0);
wire empty2 = ~|count;         // 리덕션 OR 의 부정
wire empty3 = !count;
```

Z18.7 Control flow, and what it becomes

```
// if / else -> 멀티플렉서. **양쪽 다 하드웨어로 존재한다.**
// C++ 처럼 "안 타는 가지는 실행 안 됨" 이 아니다. 둘 다 늘 계산되고
// 마지막에 mux 가 고른다. 그래서 `if (rare) 비싼연산()` 은 하드웨어에서
// 아무것도 아껴 주지 않는다.

// case -> 역시 mux. 수식어가 중요하다
unique case (state)           // 겹치는 가지가 있으면 **시뮬레이션 오류**
    IDLE: ...                 // 빠진 가지가 있어도 오류
    RUN: ...
    DONE: ...
endcase

priority case (sel)           // 위에서부터 우선순위. 겹쳐도 됨
    sel[0]: ...
    sel[1]: ...
endcase

casez (opcode)                // ? 를 don't-care 로 본다
    8'b1010_????: ...        // 상위 4비트만 맞으면 된다
endcase
// `casex` 도 있는데 **쓰지 마라** -- x 를 don't-care 로 취급해서
// 합성 전후가 달라지는 고전적 버그를 낸다.

// for -> **언롤링된다**. 루프가 아니라 하드웨어 복제다
always_comb begin
    acc = '0;
    for (int i = 0; i < NTAP; i++)
        acc = acc + x[i] * H[i];    // 곱셈기 NTAP 개가 **동시에** 생긴다
end

// 경계가 컴파일 시간에 정해져야 한다. `for (i = 0; i < n; i++)` 에서
// n 이 신호면 합성 안 된다 -- 하드웨어 개수를 못 정하므로.

// generate -> 모듈/블록을 복제한다. for 와 다르게 **구조**를 만든다
genvar g;
generate
    for (g = 0; g < NTAP; g++) begin : gen_tap    // 라벨을 **반드시** 붙인다
        tap_mul u_mul (.x(x[g]), .h(H[g]), .y(prod[g]));
```

```

    end
endgenerate
// 라벨이 없으면 계층 이름이 `genblk1` 이 되고, 나중에 탭을 하나 추가하면
// 이름이 전부 밀려서 파형·제약·커버리지가 통째로 어긋난다.
// verilator -Wall 의 GENUNNAMED 가 이것을 잡는다.

```

Z18.8 Interfaces — the one big idea with no C++ analogue

A bus has a dozen signals and they always travel together. Declaring them twelve at a time in every module is where port-list bugs come from. An interface bundles them and a modport says which direction each end sees.

```

interface axis_if #(parameter int W = 8) (input logic clk);
    logic [W-1:0] tdata;
    logic          tvalid, tready, tlast;

    // modport = 한쪽 끝에서 본 방향. 같은 다발을 양쪽이 반대로 본다
    modport src  (output tdata, tvalid, tlast, input  tready, input clk);
    modport dst  (input  tdata, tvalid, tlast, output tready, input clk);

    // 인터페이스 안에 검사도 넣을 수 있다 -- **한 번 적으면 모든 인스턴스에 걸린다**
    // (아래 assert 문법은 Z18.10)
    property valid_stable;
        @(posedge clk) (tvalid && !tready) | => $stable(tdata);
    endproperty
    assert property (valid_stable)
        else $error("tvalid 중에 tready 없이 tdata 가 바뀌었다");
endinterface

// 쓰는 쪽: 포트 열두 개가 하나가 된다
module producer (axis_if.src out);
    always_ff @(posedge out.clk) begin
        out.tvalid <= 1'b1;
        out.tdata  <= next_byte;
    end
endmodule

module top;
    logic clk;
    axis_if #(.W(8)) bus (.clk(clk));
    producer u_p (.out(bus));
    consumer u_c (.in (bus));
endmodule

```

The property embedded in the interface is the point. AXI-Stream requires that once `tvalid` is asserted, the data may not change until `tready` is seen. Written inside the interface, that rule is checked at every instance of the bus in the whole design, automatically. Written in each testbench, it is checked wherever somebody remembered.

Z18.9 Functions and tasks

Table 454. function versus task

	function	task
Can consume time	No — no @, no #, no wait	Yes
Returns a value	Yes	No (use output arguments)
Synthesisable	Yes, if it has no time control	No
C++ analogue	A constexpr-ish pure function	A coroutine — it can block and resume

```
// `automatic` 이 왜 필요한가 -- C++ 프로그래머가 가장 놀라는 자리
//
// Verilog 의 기본은 `static` 이다. 함수의 지역 변수가 **하나만 존재하고
// 모든 호출이 그것을 공유한다.** C 의 함수 안 `static int` 가 기본값인 셈이다.
// 동시에 두 번 불리면 서로의 변수를 덮어쓴다.

function automatic int unsigned clog2_up(int unsigned v);
    int unsigned r = 0;          // automatic 이라 호출마다 새로 생긴다
    while (v > 1) begin v >>= 1; r++; end
    return r;
endfunction
// **테스트벤치 함수에는 늘 `automatic` 을 붙여라.** 안 붙이면 여러
// 스레드에서 부를 때 조용히 틀린 값이 나온다.
// (SystemVerilog 의 `module` 안 기본은 static, `program`/`class` 안은 automatic)

// task: 시간을 쓴다
task automatic send_byte(input logic [7:0] b);
    @(negedge clk);
    tdata <= b;
    tvalid <= 1'b1;
    @(posedge clk);
    while (!tready) @(posedge clk); // **기다린다** -- function 은 못 하는 일
    tvalid <= 1'b0;
endtask
```

Z18.10 The verification half of the language

Everything above describes hardware. The rest of SystemVerilog is a testbench language, and it is much closer to C++ — classes, inheritance, randomisation, dynamic allocation. **None of it synthesises**, and keeping the two halves separate in your head is most of learning the language.

```
// — 어서션: 무엇이 참이어야 하는가를 적는다 —————
// 즉시 어서션 -- 절차 코드 안에서
always_ff @(posedge clk)
    if (!rst) assert (!(full && empty))
        else $error("FIFO 가 full 이면서 empty 다");

// 동시 어서션 -- 시간에 걸친 성질. 이것이 진짜 물건이다
```

```

property req_gets_ack;
    @(posedge clk) disable iff (rst)
        req |-> ##[1:8] ack;      // req 가 뜨면 1~8 사이클 안에 ack 가 온다
endproperty
assert property (req_gets_ack);
cover property (req_gets_ack);   // **정말 일어났는지**도 센다

// |-> 같은 사이클부터 (overlapping)
// |=> 다음 사이클부터 (non-overlapping)
// ##n n 사이클 뒤
// $rose $fell $stable $past edge 와 과거 값

// — 커버리지: 무엇을 **봤는지** 센다 —————
covergroup cg_sample @(posedge clk);
    cp_val: coverpoint x {
        bins neg_sat = {-128};      // 포화 경계를 실제로 밟았나
        bins neg     = {[ -127:-1]};
        bins zero    = {0};
        bins pos      = {[1:126]};
        bins pos_sat  = {127};
    }
    cp_pair: cross cp_val, cp_state; // 조합까지 봤나
endgroup
// 어서션이 "틀린 것이 없었나" 라면 커버리지는 "볼 것을 다 봤나" 다.
// 이 책의 변이 점수(Part Z1)는 세 번째 질문에 답한다:
// ***검사가 정말 무는가***. 셋이 서로를 대신하지 못한다.

// — 무작위화 —————
class packet;
    rand bit [7:0] payload [];      // 동적 배열
    rand int      len;
    constraint c_len { len inside {[1:64]};
                    payload.size() == len; }
    // 경계를 **일부러 자주** 뺏는다 -- 무작위만으로는 len==1 이 거의 안 나온다
    constraint c_edge { len dist {1 := 20, [2:8] := 40, [9:64] := 40}; }
endclass

packet p = new();
if (!p.randomize()) $fatal(1, "제약을 못 풀었다");

```

Z18.11 Classes: where SystemVerilog really is C++

```

// 검증 쪽 class 는 C++ class 와 거의 같다. 다른 점만 적는다.
class base_driver;
    // 모든 객체가 **참조**다. C++ 의 `T*` 나 `shared_ptr` 에 해당하고,
    // 값 복사(`=`)는 포인터 복사다. 깊은 복사는 직접 적어야 한다.
    protected virtual axis_if vif;    // `virtual interface` = 인터페이스 핸들

```

```

function new(virtual axis_if vif);    // 생성자 이름이 **언제나 `new`** 다
    this.vif = vif;
endfunction

// `virtual` 은 C++ 과 같은 뜻 (동적 디스패치).
// 다만 **기본이 non-virtual** 이라 붙여야 한다.
virtual task run();
    $display("base");
endtask
endclass

class fir_driver extends base_driver;    // `:` 이 아니라 `extends`
    function new(virtual axis_if vif);
        super.new(vif);                // C++ 의 base(vif) 초기화
    endfunction
    virtual task run();
        super.run();
        // ...
    endtask
endclass

// 없는 것들 (C++ 에서 오면 찾게 된다):
// * 다중 상속 없음. 인터페이스 클래스로 흉내낸다
// * 연산자 오버로딩 없음
// * 소멸자 없음 -- 가비지 컬렉션이다
// * const 멤버 함수 없음
// * 템플릿은 있다: `class stack #(type T = int);` (parameterized class)

```

Z18.12 What is and is not synthesisable

Table 455. The dividing line

Synthesisable	Not synthesisable
always_comb, always_ff, assign	initial (except FPGA memory init), final
if, case, for with constant bounds	while/forever with data-dependent exit
logic, struct packed, packed arrays, enum	class, string, real, queues ([\$]), associative arrays, dynamic arrays
function without time control	task, fork/join, @, #delay
parameter, localparam, generate	\$display, \$fopen, randomize(), assertions (they are <i>checked</i> , not built)
interface, modport	virtual interface, hierarchical references (dut.internal)
\$signed, \$unsigned, \$clog2, \$bits	\$random, \$time, \$past

The practical test, and the one this repository uses: if yosys reads it and verilator `--lint-only -Wall` is quiet, it is synthesisable. Both are free, both run in seconds, and edu/house/synth.sh runs them in that order for exactly this reason — Part Z20 walks that script line by line.

Z18.13 The house style, in ten rules

Table 456. Rules worth enforcing with a linter, and why each exists

Rule	The failure it prevents
<code>always_ff/always_comb</code> , never bare <code>always</code>	Accidental latches and missing sensitivity items.
<code><=</code> in <code>always_ff</code> , <code>=</code> in <code>always_comb</code> , never mixed	Simulation/synthesis mismatch and evaluation-order races.
One signal is driven by exactly one block	Multiple drivers — produces <code>x</code> in simulation and a short in silicon.
Always declare <code>signed</code> when the value is signed, and wrap concatenations in <code>\$signed()</code>	The half-the-input-space bug of Z18.3.
Name every <code>generate</code> block	Hierarchical names shifting when a loop bound changes.
Connect ports by name, never by position	Silent mis-connection when a port is inserted.
One module per file, file named after the module	Verilator's <code>DECLFILENAME</code> ; also how every build tool finds things.
No <code>casex</code> ; use <code>casez</code> or explicit comparison	<code>x</code> treated as don't-care, differing pre- and post-synthesis.
Reset every flop that needs a known initial value, and say which ones do not	Simulation starting in <code>x</code> and hardware starting in whatever.
No magic numbers for widths — use <code>parameter</code> and <code>\$clog2</code>	The width change that gets made in four of five places.

Nine of those ten are checked automatically by `verilator --lint-only -Wall`. Running it costs under a second and it is the highest-yield thing in the entire flow — which is why it is step one of `synth.sh` and not an afterthought.

Z19. The C++ Used for Hardware, Keyword by Keyword

The model layer in `edu/model/` is about 250 lines of C++, and almost every line uses a keyword that means something slightly different when the output is a circuit rather than a program. This part goes through them. It assumes you can write C++ and explains what each construct *costs in hardware*, which is the part no C++ book covers.

Z19.1 `inline` — and why it matters more here

```
static inline int32_t asr(int32_t v, int n) {
    return (v < 0) ? ~((-v) >> n) : (v >> n);
}
```

Table 457. What `inline` actually does

Belief	Reality
"It tells the compiler to inline the function."	It is a hint , and modern compilers ignore it for inlining decisions. <code>-O2</code> inlines small functions whether or not you write it.
"It is about speed."	Its actual required meaning is a linkage rule: it permits the same function to be defined in multiple translation units without a duplicate-symbol error. That is why it is mandatory for a function body in a header.
"In HLS it makes things faster."	In HLS it changes what hardware is built . An inlined function is flattened into the caller's datapath; a non-inlined one may become a separate module that is <i>shared</i> between call sites, with arbitration logic.

That last row is the hardware-specific part. If four call sites share one non-inlined multiply-accumulate, the tool builds one instance and a state machine that takes turns — small and slow. Inline them and you get four instances in parallel — large and fast. In C++ this is a performance micro-decision; in HLS it is an architecture decision.

In `edu/model/` everything is `static inline` in headers because the same header is compiled by `g++` (where the linkage rule is what matters) and by `bambu` (where full flattening into one datapath is what we want). `static` here means internal linkage — the function is private to each translation unit — and combined with `inline` it is the conventional way to put a small helper in a header.

Z19.2 The five meanings of `static`

C++ reused one keyword for several unrelated jobs. Three of them appear in the model code, and one of them is a bug waiting to happen in HLS.

Table 458. `static`, by position

Where it appears	What it means	Hardware consequence
On a function at namespace scope <code>static inline int32_t asr(...)</code>	Internal linkage: not visible to other translation units.	None — a linker concept.
On a variable at namespace scope <code>static const int32_t TH[4] = {...}</code>	Internal linkage, plus (with <code>const</code>) a compile-time-known value.	Large. Constant coefficients let the tool replace multipliers with shift-adds. See Z19.4.

Where it appears	What it means	Hardware consequence
On a local variable inside a function <code>static int count = 0;</code>	One instance, shared by all calls, persisting between them.	Becomes state. In HLS this infers a register or a RAM that survives across invocations — usually not what you meant, and it silently makes a pure function impure.
On a class member	Shared by all objects.	Not used in synthesisable code.
In an anonymous namespace (the modern alternative)	Same as internal linkage for names.	None.

The third row is the trap. A C++ programmer writes `static` inside a function to keep a counter cheaply. In HLS that counter becomes a register whose value carries between calls, so the generated block is no longer a function of its inputs — and the golden-model comparison that passed in C++ can fail in RTL, or worse, pass in both while the block is unusable because two instances would interfere. **In synthesisable C++, a function-local `static` is almost always a mistake.**

Z19.3 `const`, `constexpr`, and `enum`

// 이 저장소가 실제로 쓰는 세 가지, 그리고 왜 각각인가

// (1) `enum` -- 정수 상수를 묶는다. ``ipmodel.h`` 가 이걸 쓴다

```
enum {
    SAMP_F = 7,
    COEF_F = 7,
    ACC_F = SAMP_F + COEF_F,    // 다른 멤버를 참조할 수 있다
    NTAP   = 4
};
```

// 왜 `enum` 인가: ****저장 공간을 절대 차지하지 않는다****. 주소를 가질 수 없으므로
 // 컴파일러가 메모리를 잡을 여지가 없다. 옛날 C++ 에서 "enum hack" 이라
 // 불리던 관용구인데, HLS 에서는 여전히 가장 안전한 컴파일 시간 상수다.

// (2) `static const` 배열 -- 값 여러 개를 묶을 때

```
static const int32_t FIR_H[NTAP] = { -18, 111, 111, -18 };
// 배열은 enum 으로 못 만든다. `static const` 가 대신한다.
// **이 값이 컴파일 시간에 보이는 것이 면적의 핵심이다** (Z19.4).
```

// (3) `constexpr` -- 컴파일 시간 계산이 필요할 때

```
constexpr int32_t sat_hi(int n) { return (1 << (n - 1)) - 1; }
static const int32_t HI = sat_hi(8);           // 127, 컴파일 시간에 계산됨
// `const` 는 "안 바꾼다" 이고 `constexpr` 은 "컴파일 시간에 값을 안다" 이다.
// 둘은 다르다:
const int a = rand();           // 합법. 런타임 값인데 안 바뀔 뿐
constexpr int b = rand();       // **컴파일 오류**. 컴파일 시간에 알 수 없다
```

Table 459. Which to use, in synthesisable C++

Need	Use	Why not the others
A single integer constant	<code>enum</code> or <code>constexpr</code>	<code>static const int</code> also works but may take storage if its address is ever taken.

Need	Use	Why not the others
An array of constants	<code>static const T[]</code>	enum cannot hold arrays. Mark it <code>const</code> or the tool must assume it can change and builds a RAM.
A value computed from other constants	<code>constexpr</code> function	A normal function may not be evaluated at compile time, so the result is not a constant to the HLS tool.
A run-time-settable coefficient	A function parameter, deliberately	This is the opposite choice and it costs real multipliers — make it consciously.

Z19.4 Why `const` on the coefficients is worth hundreds of gates

Worked example 72. Constant multiply versus variable multiply

Given. The filter computes `a1 * 111`. In one version 111 is a `static const`; in the other it arrives as a function parameter.

Method. A constant multiply can be expanded into shifts and adds at compile time. $111 = 64 + 32 + 8 + 4 + 2 + 1$, so it is a sum of six shifted copies — or, better, $111 = 128 - 16 - 1$, which is three terms.

Constant: about 2 adders and 1 subtractor of 9–17 bits — roughly 40–50 LUT4 on iCE40. Variable: a full 9×8 array multiplier, roughly 150–200 LUT4, or a hard DSP block where one exists. The design consequence for a sellable IP: if customers need programmable coefficients, you pay for real multipliers and you must say so in the datasheet. If the coefficients are fixed at build time, you can offer a block a quarter the size. These are two different products, and the difference is one `const`.

How this is got wrong. The trivial explanation to kill is “the tool is smart.” It is not being smart; it is being given different information. Make the coefficient a parameter and the same tool produces the big version, because it now must handle every possible coefficient value. The measured evidence is in Z15: the tuned design used 97 `SB_CARRY` and **zero** hard multipliers, because every multiply had a compile-time-constant operand.

Z19.5 Fixed-width types, and integer promotion

```
#include <stdint.h>      // int8_t, int16_t, int32_t, uint32_t ...

// `int` 은 쓰지 마라 -- 크기가 구현마다 다르고, HLS 에서는 **포트 폭이 된다**.
// Z15 의 실측: 인자를 `int` 로 두면 포트가 32비트가 되어 면적이 3.6배가 됐다.

// 정수 승격 (integer promotion) -- C++ 이 조용히 32비트로 올리는 규칙
int8_t  a = 100, b = 100;
auto    c = a + b;        // c 의 타입은 int8_t 가 **아니라 int** 다!
// a+b = 200 이고, int8_t 였다면 -56 으로 넘쳤을 것이다. int 라서 200 이 된다.
//
// 이것이 모델과 RTL 이 갈라지는 대표적인 자리다:
//   C++ 모델: 200 (int 로 승격돼서)
//   RTL:      -56 (8비트로 짤으면)
// **모델이 하드웨어보다 관대하다.** 그래서 `ipmodel.h` 는 폭을 손으로
// 못박는다 -- `sat(v, 8)` 이 그 일을 한다.

// 규칙: `char`·`short`·`bool` 과 그 unsigned 판은 산술 연산 전에
// 전부 `int` 로 올라간다. `int` 보다 큰 타입은 안 올라간다.

// 부호 있는 것과 없는 것을 섞으면 더 나쁘다
```

```
int32_t x = -1;
uint32_t y = 1;
bool z = (x < y);    // **false** 다. x 가 unsigned 로 변환돼 4294967295 가 된다
// 컴파일러가 -Wsign-compare 로 경고한다. **경고를 켜고 오류로 다뤄라.**
```

Z19.6 References, pointers, and what they become

// C++ 의 세 가지 전달 방식과, HLS 가 각각 무엇으로 만드는가

```
int32_t f1(int32_t x);           // 값 전달 -> 입력 포트 하나
int32_t f2(const int32_t *x);    // 포인터 -> **메모리 인터페이스**
int32_t f3(const int32_t &x);    // 참조 -> 값 전달과 같게 취급되는 경우가 많다
void f4(int32_t &out);          // 비-const 참조 -> 출력 포트
```

// 포인터가 위험한 이유 -- `fir\_top.cpp` 가 그래서 스칼라 넷을 받는다:

```
//
// int fir_top(const int *x) -> bambu 가 주소·요청·응답 포트를 만든다.
//                               재는 것이 FIR 이 아니라 메모리 컨트롤러가 된다
// int fir_top(int,int,int,int) -> 포트 넷. 데이터패스만 남는다
//
// 그래서 모델 안에서는 배열(`const int32_t *x`)을 쓰고,
// **HLS 최상위에서만** 스칼라로 퍼서 넘긴다. 안쪽은 인라인되므로
// 포인터가 남지 않는다.
```

```
// 합성 가능한 C++ 에서 **없는** 것들:
// * 동적 할당 (new/delete/malloc) -- 하드웨어에 힘이 없다
// * 재귀 -- 깊이가 컴파일 시간에 안 정해지면 회로 크기를 못 정한다
// * 가상 함수 -- 런타임 디스패치는 하드웨어에 없다
// * 함수 포인터 -- 같은 이유
// * 예외 (try/catch) -- 스택 되감기가 없다
// * std::vector, std::string, std::map -- 전부 동적 할당이다
```

The list of absences is the real lesson. Synthesisable C++ is a *subset*: fixed-size data, no dynamic anything, no indirection that cannot be resolved at compile time. What remains is essentially C with templates — which is why the model layer looks the way it does, and why a C++ programmer's instincts about abstraction have to be held in check.

Z19.7 Templates — the one abstraction that survives

```
// 템플릿은 **컴파일 시간에 전부 풀린다**. 그래서 합성된다.
// 하드웨어에서 템플릿 인자는 곧 **비트폭과 개수**다.
```

```
template<int W>
static inline int32_t sat_t(int32_t v) {
    constexpr int32_t hi = (1 << (W - 1)) - 1;
    constexpr int32_t lo = -hi - 1;
    return v > hi ? hi : (v < lo ? lo : v);
}
// sat_t<8>(x) 와 sat_t<18>(x) 는 **서로 다른 하드웨어**를 낳는다.
```

```
// C++ 의 `template<int>` 가 SystemVerilog 의 `parameter` 와 같은 자리다.

// 탭 수까지 템플릿으로 빼면 4탭과 16탭이 한 소스에서 나온다
template<int N>
static inline int32_t fir_n(const int32_t *x, const int32_t *h) {
    int32_t acc = 0;
    for (int i = 0; i < N; i++) acc += x[i] * h[i];    // N 이 상수 -> 언롤됨
    return acc;
}

// 그런데 대가가 있다 -- 실측이다.
// survey/synth/합성결과.md: `ap_fixed` 로 된 복소 8x8 Cholesky 는
// Bambu 프론트엔드에서 **40분 타임아웃(rc=124)** 이 났다.  템플릿 깊이가
// 깊어지면 HLS 도구가 프론트엔드에서 죽는다.
//
// 규칙: **얕은 템플릿은 공짜, 깊은 템플릿은 도구를 죽인다.**
// `template<int W>` 정도는 안전하고, 템플릿이 템플릿을 부르는 수학
// 라이브러리는 위험하다.
```

Z19.8 Namespaces and ::, the C++ side

```
namespace fir {
    enum { NTAP = 4 };
    static const int32_t H[NTAP] = { -18, 111, 111, -18 };
    static inline int32_t tap(const int32_t *x);
}

// 쓰는 쪽 -- SystemVerilog 의 package 와 문법이 거의 같다
int32_t y = fir::tap(x);
int      n = fir::NTAP;

using namespace fir;    // SV 의 `import fir_pkg::*;`
int32_t y2 = tap(x);

// `::` 의 다른 얼굴들
::global_thing          // 전역 네임스페이스 (SV 의 $unit:: 에 해당)
std::int32_t             // 표준 라이브러리
MyClass::method          // 클래스 멤버
MyClass::Nested::value   // 중첩
enum class E { A };      E::A // 범위 있는 enum (SV 의 state_e::IDLE 과 같다)
```

Table 460. ::, side by side

Purpose	C++	SystemVerilog

Global scope	::name	\$unit::name
Class member	C::m	C::m (verification classes)
Not a thing	—	There is no -> for scope; SystemVerilog uses . for instance members and hierarchy

So the answer to “I only know C++, what is ::?” is: it is the same operator you already know, and SystemVerilog borrowed it deliberately. The construct behind it — package — is the direct analogue of namespace, with one difference that matters: a SystemVerilog package must be *compiled before* its users, because there is no two-pass name resolution and no forward declaration.

Z19.9 The flags the build actually uses

골든모델을 컴파일할 때

```
g++ -O2 -I. -o vectors vectors.cpp
```

```
# -O2    최적화.   등가성 전수 확인이 29.7초가 된 것이 이 덕이다.
#       -O0 이면 수 분이 걸린다 -- 그러면 전수를 포기하게 되고,
#       포기하면 표본으로 내려간다.  **최적화 플래그가 검증 전략을 바꾼다.**
# -I.    헤더 탐색 경로.  `fir.h` 를 찾는다
```

```
# 커 둘 만한 경고 -- 모델과 RTL 이 갈라지는 자리를 짚는다
g++ -O2 -Wall -Wextra -Wsign-compare -Wconversion -Werror ...
# -Wconversion    폭이 줄어드는 암묵 변환을 경고한다.  HLS 에서 이것이
#                  곧 비트 잘림이다
# -Wsign-compare   Z19.5 의 부호 섞임
# -Werror          경고를 오류로.  경고는 안 읽히고 오류는 읽힌다
```

```
# HLS 로 넘길 때 -- 같은 헤더, 다른 도구
bambu --top-fname=fir_top_tuned -I/home/user/SE/edu/model \
      --clock-period=3 --reset-level=high --reset-type=sync \
      fir_top_tuned.cpp
```

```
# --top-fname      어느 함수가 최상위 모듈이 되는가
# -I              g++ 와 **같은** 경로.  같은 헤더를 읽는다는 뜻이다
# --clock-period   목표 주기(ns).  Z15 에서 이 숫자 하나로
#                  마이크로아키텍처 다섯 개를 얻었다
# --reset-level    active high/low.  **기본값이 low 라서** 한 번 물렸다
# --reset-type     sync/asnc/no
```

The two commands read the same header with the same include path. That is the whole design of the model layer in one line of shell: if the paths ever diverge, the golden model stops being the thing that was synthesised, and the comparison becomes decoration.

Z20. The Free Toolchain, Command by Command

Every number in Parts Z14–Z19 was produced by tools that cost nothing and install from a package manager. A one-person design house can take a block from C++ to a placed-and-routed netlist with a timing number without a single licence. This part is how, command by command, with the real output each one produces.

Table 461. The toolchain, as measured in this container

Tool	Version here	Job	Licence
Verilator	5.020	Lint, and fast C++-based simulation	LGPL-3 / Artistic-2
Icarus Verilog	12.0	Event-driven simulation of the full language	GPL-2
Yosys	0.33	Synthesis: RTL → gate netlist	ISC
nextpnr-ice40	0.6	Place and route, static timing	ISC
PandA Bambu	2024.10	High-level synthesis: C/C++ → RTL	GPL-3
GCC	g++ -O2	Compiles the golden model	GPL-3

Two things are missing from that list and it is worth being honest about them. There is **no free sign-off static timing analyzer for ASICs** (OpenSTA exists but was not available here), and there is **no free formal equivalence checker**. For FPGA work the gap does not bite; for an ASIC tape-out it does, and Part Y13 covers what that means commercially.

Z20.1 Step one: lint, because it is the cheapest

```
verilator --lint-only -Wall --top-module fir4_hand edu/model/fir4_hand.v
```

Table 462. What the flags do

Flag	Meaning	Why
--lint-only	Parse and check; do not build a simulator.	Runs in well under a second. This is the whole point.
-Wall	Enable all the style and width warnings.	The default set is too quiet. -Wall is what industry actually turns on.
--top-module	Name the top of the hierarchy.	Without it, a file with several modules gives confusing 'no top' errors.

The warnings that matter most, and what each is telling you:

Table 463. Verilator warnings you will actually see

Warning	Means	Take it seriously?
WIDTHEXPAND / WIDTHTRUNC	An assignment or operation changes bit width implicitly.	Yes, always. This is the class of bug Z16.7 spent five derivation steps preventing. Every silent truncation lives here.
UNUSED SIGNAL	A signal is declared or driven and never read.	Usually. Either it is dead logic (remove it) or you forgot to connect something. Suppress deliberately with a comment when a port is genuinely reserved.
LATCH	Combinational block does not assign in all paths.	Yes. Almost never intended. See Z18.5.
MULTIDRIVEN	Two blocks drive one signal.	Yes. This is a hard bug: x in simulation, contention in silicon.

Warning	Means	Take it seriously?
BLKSEQ / COMBDLY	Blocking assignment in sequential logic, or vice versa.	Yes. The race of Z18.4.
DECLFILENAME	Module name does not match file name.	Cosmetic, but fix it — every build system assumes the convention.
GENUNNAMED	Unnamed generate block.	Fix it. Hierarchical names shift when loop bounds change.
SYNCASYNCNET	A net is used as both sync and async reset.	Investigate. Usually a real reset-architecture problem.

Worked example 73. Reading a lint report on generated code

Given. Running the command above on Bambu's generated `fir_top.v` returns 19 warnings: 7 `WIDTHEXPAND`, 6 `UNUSED SIGNAL`, 3 `WIDTHTRUNC`, 1 `UNUSED PARAM`, 1 `SYNCASYNCNET`, 1 `DECLFILENAME`.

Method. Separate warnings that indicate a defect from warnings that indicate a generator's house style. Effectively **all 19** are style, not defects. Generated RTL uses parameterised width-adaptor modules, so `WIDTHEXPAND` and `UNUSED SIGNAL` appear wherever a generic module is instantiated narrower than its maximum. The same reasoning applies to hand-written RTL with a different conclusion: there, a clean `-Wall` report is achievable and should be a release gate. `edu/model/fir4_hand.v` is clean.

How this is got wrong. The wrong conclusion is “lint is useless on generated code.” The right one is that you must **lint the generator's output once**, triage it, and then **watch for new warning types**. A `WIDTHTRUNC` that was not there yesterday is a real signal; the same six `UNUSED SIGNAL` every build is noise. Counting warnings by type — which is what `synth.sh` prints — makes the difference visible.

Z20.2 Step two: simulate

```
# 컴파일 -- 소스 여러 개를 한 실행파일로
iverilog -g2012 -DDUT=fir4_hand -o a.out edu/model/fir_tb.v edu/model/fir4_hand.v

# -g2012 SystemVerilog-2012 문법을 켜다. **안 켜면 always_ff 부터 막힌다**
# -D 매크로 정의. C 의 -D 와 같다. 여기서는 테스트벤치 하나로
# 손RTL 과 HLS RTL 을 갈아 끼우는 데 쓴다
# -o 출력 파일
# -s <톱> 톱 모듈 지정 (여러 개일 때)

# 실행 -- vvp 가 iverilog 의 가상머신이다
vvp a.out

# 결과
# 잔것 400 틀림 0

# 파형을 보고 싶으면 테스트벤치에 이것을 넣는다
# initial begin $dumpfile("w.vcd"); $dumpvars(0, tb); end
# 그리고 gtkwave 로 연다 (이 컨테이너에는 없다 -- GUI 가 없으므로)
```

Verilator can also simulate, and it is 10–100× faster than Icarus because it compiles to C++ rather than interpreting events. The trade is that Verilator's simulation is 2-state and cycle-based: it will not show you x propagation, which is exactly the thing you want to see when debugging a reset problem. **Use Icarus to find the bug and Verilator to run the regression.**

Z20.3 Step three: synthesise with Yosys

```
yosys -p "read_verilog -sv edu/model/fir4_hand.v; \
        hierarchy -check -top fir4_hand; \
        proc; opt; fsm; opt; memory; opt; techmap; opt; \
        stat"
```

Table 464. The Yosys script, pass by pass

Pass	What it does
read_verilog -sv	Parse. -sv enables SystemVerilog; without it a lways_ff is a syntax error.
hierarchy -check -top M	Resolve the module tree from M downward. -check makes a missing module an error rather than a black box — without it, a typo in a module name silently synthesises to nothing.
proc	Convert always blocks into multiplexers and registers. This is where <= becomes a flip-flop.
opt	Constant folding, dead-code removal, simplification. Run it between every other pass; it is cheap.
fsm	Detect state machines and re-encode them.
memory	Turn array accesses into RAM primitives.
techmap	Map to generic gates (\$_AND_, \$_XOR_, ...).
stat	Print the cell count. Do not pass -q to yosys — it swallows this output, which was measured here the hard way.

The real output for the hand-written filter:

```
=== fir4_hand ===
```

```
Number of wires:          268
Number of wire bits:      1681
Number of public wires:   14
Number of public wire bits: 97
Number of cells:          780
  $_AND_                   340
  $_MUX_                   15
  $_NOT_                   10
  $_OR_                    142
  $_SDFF_PP0_              9
  $_XOR_                   264
```

Reading that report without guessing

	Step	Justification
1	<code>\$_SDFF_PP0_</code> × 9 — nine synchronous flip-flops, positive edge, positive reset, reset-to-0.	<i>The design has exactly nine state bits: <code>done_port</code> (1) plus <code>return_port</code> (8). The number matching the count you expected is the first thing to check — a surprise here means inferred state you did not intend.</i>
2	<code>\$_XOR_</code> × 264 dominates the combinational logic.	<i>XOR is the sum output of a full adder (Z17.6). Two 9-bit adds plus a 17-bit add plus the constant-multiply shift-add network accounts for it.</i>
3	<code>\$_AND_</code> × 340 and <code>\$_OR_</code> × 142 are the carry logic.	<i><code>cout = (a AND b) OR (cin AND (a XOR b))</code> — two ANDs and an OR per bit.</i>
4	<code>\$_MUX_</code> × 15 is the saturation.	<i>Two comparisons selecting between three 8-bit values. This is the gate-level price of saturating rather than wrapping, as Z17.7 predicted.</i>
5	But 780 generic cells is not the area of the design.	<i>These are technology-independent gates. The device has 4-input lookup tables and a dedicated carry chain, so the mapping in the next step collapses this dramatically — 780 generic cells became 257 iCE40 cells. Never quote generic cell counts as area.</i>

Z20.4 Step four: map to a real device

```
yosys -p "read_verilog -sv fir4_hand.v; \
        synth_ice40 -top fir4_hand -json fir4_hand.json; \
        stat"
```

```
# synth_ice40 은 위의 긴 스크립트를 **대신한다** -- 읽기부터 기술 매핑까지
# 한 명령이다. 다른 판을 쓰면 명령만 바꾼다:
# synth_ice40      Lattice iCE40
# synth_ecp5       Lattice ECP5   (더 크다. nextpnr-ecp5 와 짝)
# synth_gowin      Gowin
# synth_xilinx     Xilinx 7-series (nextpnr-xilinx 는 실험적이다)
# synth_intel      Intel/Altera
# ABC9 기반 매핑을 쓰려면 `-abc9` 를 붙인다 (보통 더 작고 빠르다)
```

```
=== fir4_hand ===
Number of cells:          257
  SB_CARRY                48
  SB_DFFSR                9
  SB_LUT4                 200
```

Now the numbers mean something physical. SB_LUT4 is a 4-input lookup table, SB_CARRY is one bit of the dedicated carry chain, SB_DFFSR is a flip-flop with set/reset. The 48 carry cells are the adders using hardware the fabric provides for free — which is why the generic 780 collapsed to 257, and why the gate-counting exercise in Z17.6 explains the *structure* but not the *number*.

Z20.5 Step five: place, route, and get a real frequency

```
nextpnr-ice40 --hx8k --package ct256 --json fir4_hand.json \
    --pcf-allow-unconstrained --placer heap --freq 300 --seed 1
```

Table 465. The flags that change the answer

Flag	Meaning	Why it matters
--hx8k --package ct256	Device and package.	Pin count is a real constraint. Measured here: up5k/sg48 has 39 I/O and refused to place a design needing 43, with Unable to find a placement location. That is not a quality problem with the design.
--pcf-allow-unconstrained	Allow pins with no physical assignment.	Needed when you are measuring a block rather than building a board.
--placer heap	Analytic placer.	Better and more repeatable than the default SA placer.
--freq 300	Target frequency in MHz.	Without this the target defaults to 12 MHz and the tool stops optimising the moment it passes — the reported Fmax then reflects routing luck, not the design.
--seed N	Placement random seed.	Run three and report the spread. A single seed is a sample of one.

Info: ICESTORM_LC: 211/ 7680 2%

Info: Max frequency for clock 'clock\$SB_IO_IN\$glb_clk': 455.79 MHz (PASS at 12.00 MHz)

Worked example 74. Why that 455.79 MHz was not usable and 47 MHz was

Given. Placing the hand-written filter directly gives 455.79 MHz. Wrapping it in a registered timing shell and re-placing gives 47.4 MHz. Same design.

Method. Ask which paths the tool is measuring in each case.

Without the shell the design has 9 flops, all at the output. The only register-to-register paths are trivial, and the real datapath runs from an **input pin** to those flops — unconstrained, therefore unreported. With the shell, every path starts and ends at a flop, so the 47.4 MHz is the actual combinational depth of the filter. The general rule: **a frequency number is meaningless unless you can say which two registers the path runs between.** Ask that question of every Fmax anyone quotes you, including your own.

How this is got wrong. The 455.79 MHz figure is stable across seeds and looks entirely credible. A reproducible measurement of the wrong path is the most dangerous kind, because every instinct says to trust it. What exposed it was a contradiction, not a tool warning: adding pipeline registers made the reported frequency *fall*, and more registers cannot make a design slower.

Z20.6 Step six: HLS, if you are generating the RTL

```
bambu --top-fname=fir_top_tuned \
    -I/home/user/SE/edu/model \
    --clock-period=3 \
    --reset-level=high --reset-type=sync \
    fir_top_tuned.cpp
```

```
# --top-fname    최상위가 될 C 함수.  **이것이 모듈 이름이 된다**
# -I            헤더 경로.  g++ 와 **같은 경로**를 줘야 같은 모델이 된다
# --clock-period  목표 주기 (ns).  스케줄링이 여기에 맞춰진다.
#              Z15 에서 10·6·3·2·1 로 풀어 무릎을 찾았다
```

```
# --reset-level      high / low.  **기본이 low 다** -- 집 관례와 다르면 여기서 맞춘다
# --reset-type       sync / async / no
# --simulate         내장 테스트벤치로 돌려 본다 (골든이 따로 있으면 안 써도 된다)
# --device-name      목표 소자. 타이밍 추정에 쓰인다

# 안 되는 것들 -- survey/synth/합성결과.md 의 1변수 대조
# #pragma HLS ...    rc=11. Xilinx 방언을 안 받는다
# hls::stream        rc=1.  FixStructsPassedByValue 에서 크래시
# 깊은 ap_fixed 템플릿 rc=124. 프론트엔드 40분 타임아웃
```

Z20.7 One command that runs all of it

edu/house/synth.sh is the whole flow in one script. It is written to be read as well as run, and two of its choices came from being wrong first.

```
bash edu/house/synth.sh <file.v> <top_module> [--pnr]
```

예

```
bash edu/house/synth.sh edu/model/fir4_hand.v fir4_hand --pnr
```

출력

```
# == 1. verilator lint ==
#   경고+오류 0
#   lint rc=0
# == 2. yosys 기술독립 합성 ==
#   Number of cells: 780 ...
# == 3. yosys ice40 매핑 ==
#   SB_LUT4 200, SB_CARRY 48, SB_DFFSR 9
# == 4. nextpnr 배치·배선 ==
#   ICESTORM_LC: 211/7680, Max frequency 47.4 MHz
```

Table 466. Two things the script does that look fussy and are not

Choice	What went wrong without it
Tool output goes to a file , then is filtered — never piped straight into head.	head closes the pipe, the tool dies of SIGPIPE, and the exit code comes back 141 . A lint that passed and a lint that crashed became indistinguishable. Measured here.
Cell counts are extracted from inside the stat block, not by grepping the whole log.	Yosys prints Generating RTLIL representation for module \SB_LUT4 while loading its cell library. A naive grep SB_LUT4 counts those lines as if they were cells.

Both are the same failure in different clothes: **a measurement harness that reports a plausible number when it has actually failed**. That is the defect this whole book is organised against, and it turns out to be just as easy to build into a twelve-line shell script as into a verification environment.

Z20.8 Installing the lot

Debian / Ubuntu -- 앞의 넷은 패키지가 있다

```
sudo apt install verilator yosys nextpnr-ice40 iverilog gtkwave
```

```
# Bambu 는 패키지가 없다. 소스에서 짓는다 (이 컨테이너에서 한 일이다)
sudo apt install gcc-multilib libc6-dev-i386 gcc-13-plugin-dev \
                  clang-16 llvm-16-dev libclang-16-dev \
                  autoconf automake libtool
git clone --recursive https://github.com/ferrandi/PandA-bambu.git
# 막혔던 자리들 (survey/synth/합성결과.md 에 전부 적혀 있다):
# * --depth 1 로 클론하면 서브모듈이 빠져 Makefile.in 이 없다
# * ext/Coin-Cbc 와 ext/lpsolve5 는 선택인데도 automake 가 디렉터리 존재를 요구한다
# -> 빈 디렉터리를 만들면 넘어간다
# * clang 은 16 이어야 한다. 18 은 너무 새것이라 configure 가 거른다
```

The install list is short and the whole thing fits on a laptop. That is the point of this part: the barrier to running a real IP flow is not money any more. What the free tools do not give you is ASIC sign-off timing, formal equivalence, and somebody to call — and those are exactly the things Part Y13 says to budget for when a block stops being an exercise and starts being a product.

Y1. MIPI CSI-2 and DSI, Worked as a Deliverable

Every phone camera, most automotive cameras and a large fraction of embedded vision sensors speak CSI-2; every phone display and most embedded panels speak DSI. The two share a PHY and a packet structure, which is why a design house that builds one has most of the other. This part works the numbers a customer will ask for, and states where the answers come from.

The commercial boundary is the PPI: above it is soft RTL a design house can sell,
below it is a hard macro tied to one foundry process.

Figure 61. The CSI-2 / DSI stack, with the boundary that determines what a soft-IP vendor can actually sell.

Y1.1 Bandwidth: from a sensor specification to a lane count

This is the first calculation a customer will do with your datasheet, so it must be the first one in it. It is also the calculation that decides whether your block is in the design at all.

Table 467. Required D-PHY bandwidth and lane count at 2.5 Gbps per lane

Mode	Mpixel/s	bits/pixel	Payload (Gbps)	With 15 % overhead (Gbps)	Lanes at 4 Gbps/lane	Lanes at 2.5 Gbps/lane
1080p30	62.21	12	0.7465	0.8585	1	1
1080p60	124.4	12	1.493	1.717	1	1
4K30	248.8	12	2.986	3.434	1	2
4K60	497.7	12	5.972	6.868	1	3
8MP automotive 30	248.8	16	3.981	4.579	1	2
12MP still burst	360	14	5.04	5.796	1	3

The 15 % allowance covers line blanking, packet headers and footers, and the low-power intervals between bursts. **It is an assumption and it belongs in the datasheet beside the number it produced;** a customer with a different blanking ratio will get a different lane count and should be able to see why.

Worked example 75. Why the overhead is not a fixed percentage

Given. A 1920×1080 frame, 12 bits per pixel, RAW12 packing. Each line is one long packet: 4 bytes of header, the payload, and 2 bytes of footer. Between lines the link may drop to low-power state and return, costing $T_{LPX} + T_{HS-PREPARE} + T_{HS-ZERO} + \text{sync}$, taken here as 300 ns.

Method. Compute the per-line overhead in bytes and in time, then express it as a fraction. The fraction depends on the line length, which is why a single percentage cannot be right for every mode.

Payload bytes per line	2,880
Packet header + footer	6 bytes
Packet overhead	0.208 %
Line payload time at 4 lanes × 2.5 Gbps	2.304 μs
LP transition cost per line	0.3 μs
Transition overhead	13 %
Total overhead for this mode	13.2 %
Same for a 320-pixel-wide line	79.4 %

How this is got wrong. By quoting one efficiency figure for the whole product. The overhead is dominated by a per-line *constant*, so efficiency collapses for short lines: a narrow region-of-interest readout — exactly what a machine-vision customer does — can spend more time in transitions than in data. The design response is to **stay in high-speed state across lines** when the blanking interval is short, which the specification permits and which many controllers do not implement. That feature is worth naming in a datasheet because a competitor's block that lacks it will lose the ROI benchmark.

Y1.2 The D-PHY state machine and its timing parameters

Table 468. D-PHY lane states and what each costs

State	Electrical	Purpose	Entry cost
LP-11 (Stop)	Both lines high, 1.2 V single-ended	Idle	—
LP-01 / LP-00	Low-power signalling	Request and bridge states	T_{LPX} per transition, min 50 ns
HS-0 / HS-1	200 mV differential about a 200 mV common mode	Data burst	$T_{HS-PREPARE} + T_{HS-ZERO} + \text{sync}$, 150–300 ns
ULPS	LP-00 held	Ultra-low power; clock may stop	$T_{WAKEUP} \geq 1 \text{ ms}$ — a millisecond, not a microsecond
Escape mode	LP pulse-coded	Trigger, LPDT side-channel	Slow by design

The 1 ms ULPS wake-up is a system-level number that routinely surprises integrators. A design that powers the link down between frames to save energy cannot wake it in a line blanking interval; it can only wake it in a frame interval, and only if the frame rate leaves a millisecond spare. 30 fps gives 33 ms per frame, so it fits; a 240 fps burst mode does not.

Power state transitions have latencies that are three to five orders of magnitude apart — 50 ns for LPX, 1 ms for ULPS — and a power management policy that treats them as interchangeable will either waste energy or drop frames.

Table 469. D-PHY timing parameters evaluated at three lane rates (ns)

Parameter	Specified as	at 1.0 Gbps	at 1.5 Gbps	at 2.5 Gbps
T_LPX	≥ 50	50	50	50
T_HS-PREPARE	$40 + 4 \times UI \dots 85 + 6 \times UI$	44	42.67	41.6
T_HS-ZERO	$\geq 145 + 10 \times UI$	155	151.7	149
T_HS-TRAIL	$\geq \max(8 \times UI, 60 + 4 \times UI)$	64	62.67	61.6
T_HS-EXIT	≥ 100	100	100	100
T_CLK-PRE	$\geq 8 \times UI$	8	5.333	3.2
T_CLK-POST	$\geq 60 + 52 \times UI$	112	94.67	80.8

These values are computed from the formulae as written here and have not been checked against a current copy of the MIPI D-PHY specification, which is a paid document this repository has not obtained. Treat the shape as correct and the constants as requiring confirmation before they enter an implementation.

On quoting a specification you have not read. The table above is deliberately marked. A design house that builds a MIPI controller buys the specification; there is no substitute and no legitimate way around it. Writing formulae from secondary sources into RTL is how a block comes to fail interoperability at a plugfest, and the failure is expensive precisely because it is found late and in public. **The correct entry in a project plan is a line item for the specification and for membership, not an assumption that the numbers can be inferred.**

Y1.3 Packet structure, ECC and CRC — and why both exist

Why the header has ECC and the payload has CRC

	Step	Justification
1	The short packet header is 4 bytes: data identifier, two word-count bytes, and one ECC byte.	<i>CSI-2 packet structure.</i>
2	The ECC is a Hamming code over the preceding 24 bits, giving single-error correction and double-error detection.	<i>From Part X10's bound: 24 data bits need $r = 5$ for correction, plus one overall parity, which fits in the byte with two bits spare.</i>
3	A corrupted header is unrecoverable at any higher layer , because the word count tells the receiver where the packet ends.	<i>A wrong length desynchronises the stream for the remainder of the frame. Correction, not detection, is therefore required here.</i>
4	The payload carries a 16-bit CRC and no correction .	<i>A corrupted pixel is one bad pixel; the frame continues. Detection lets the application decide, and correction would cost far more for far less.</i>
5	The asymmetry is a design principle, not a quirk of this standard.	<i>Spend correction where a failure is structural and detection where it is local. The same reasoning produced the parity-plus-reload answer for configuration memory in Part X10.</i>

Problem. A customer reports occasional frame corruption that disappears when they reduce the lane rate. Your ECC error counter is zero and your CRC counter is non-zero. What does that tell you, and what would the opposite pattern tell you?

Solution. CRC errors without ECC errors mean the *payload* is being corrupted while the headers survive. That is a strong hint, because headers and payload travel the same wires but not the same way: headers occur at the start of a burst, just after the HS settle time, and are short; payload is long and continuous. Corruption that spares the header and hits the payload points at something that accumulates over a burst — **clock drift or an under-specified $T_{\text{HS-SETTLE}}$ window that is fine for the first bytes and drifts later**, or an SSC/jitter interaction, or simply insufficient eye at the sampling point for long runs. The opposite pattern, ECC errors without CRC errors, would point at the *transition*: the receiver is mis-sampling the first bytes after leaving low-power state, which is the classic symptom of an incorrect settle-time programming or of a PHY that reports ready too early. **The instrumentation that makes this diagnosis possible — separate, readable counters for header and payload errors, with the ability to capture the first failing packet — is a feature to design in, not a debug hack; it is also a strong differentiator in a datasheet.**

Y1.4 What the repository's real CSI-2 source shows

The code appendix of this book reproduces **32,676 lines** across 55 files of a working MIPI CSI-2 receiver written for FPGA fabric. It is worth reading for one reason above all: it shows how much of the block is *not* the protocol. Word alignment, lane de-skew, the byte-to-pixel unpacker and the clock-domain crossing to the pixel clock take more code than the packet decoder.

Table 470. The twelve largest files of the CSI-2 receiver in the corpus

File	Lines
line_ram_dp.v	5,781
out_line_ram_dp.v	5,781
mipi_csi_phy.v	4,697
out_line_ram_ldp.v	4,635
uvc.c	2,094
cyfxtx.c	1,188
cyfxuvcdscr.c	1,024
sensor_imx219.c	587
debayer_filter.v	458
line_ram_dp.v	373
debayer_filter.v	350
tb_mipi_bridge.v	334

Counted from the indexed corpus at build time.

Graduate · What a design house adds on top of an open-source receiver like this one. The open block demonstrates the datapath. What it does not contain is what a customer pays for: a register map with a defined reset state and an IP-XACT description; error counters and an interrupt controller; support for more than one virtual channel and for the data types the customer's sensor actually emits; a verification environment with the protocol checkers and a compliance test list; synthesis and timing closure at a specified frequency in a named process with reports; lint and CDC sign-off; and documentation that lets an integrator finish without calling. **Each of those is weeks of work, and together they are the product.** A design house that believes the RTL is the product will price the work at a fraction of its cost and deliver something a customer cannot integrate.

Table 471. An honest effort estimate for a sellable CSI-2 receiver, one engineer

Activity	Weeks	Share of a person-year (%)
Specification study and register map	3	5.77
RTL: protocol layer	4	7.69
RTL: lane management and de-skew	3	5.77
RTL: PPI adaptation and CDC	3	5.77
C reference model for the packet layer	2	3.85
Verification environment and checkers	6	11.5
Directed and random test suites	5	9.62
Lint, CDC and synthesis sign-off	3	5.77
Timing closure at target frequency	2	3.85
IP-XACT packaging and integration guide	2	3.85
Documentation and datasheet	3	5.77
Customer support allowance, first year	6	11.5

*Total 42 weeks — about 0.8 person-years. **Verification and everything downstream of RTL is 64 % of it.** An estimate that counts only the RTL rows produces 10 weeks and is the reason first-time IP vendors run out of money.*

Y2. PCI Express, Generations 3 to 6, Worked

PCIe is the interface a design house is most likely to be asked for and least likely to build from scratch, because the controller is enormous and the compliance burden is severe. It is nevertheless worth understanding in detail, because almost every block a design house sells will sit behind one, and the properties of that link — its latency, its credit behaviour, its error model — propagate into the specification of whatever is attached.

Y2.1 The rate table, computed rather than remembered

Table 472. PCIe generations: raw rate, encoding and usable bandwidth

Generation	GT/s per lane	Encoding	Encoding efficiency	GB/s per lane (one direction)	GB/s at x16	Modulation
Gen1	2.5	8b/10b	0.8	0.25	4	NRZ
Gen2	5	8b/10b	0.8	0.5	8	NRZ
Gen3	8	128b/130b	0.9846	0.9846	15.75	NRZ
Gen4	16	128b/130b	0.9846	1.969	31.51	NRZ
Gen5	32	128b/130b	0.9846	3.938	63.02	NRZ
Gen6	64	242B FLIT / PAM4	0.9453	7.562	121	PAM4

Computed from the transfer rate and the encoding efficiency alone; protocol overheads (TLP headers, DLLPs, ordered sets) are additional and Y2.3 computes them. The 8b/10b to 128b/130b change at Gen3 is why Gen3 is more than 1.6× Gen2 despite the rate being only 1.6×.

Worked example 76. Why Gen6 went to PAM4 and what it cost

Given. Gen5 runs 32 GT/s NRZ; Gen6 runs 64 GT/s. The channel budget is roughly unchanged, because the connectors and boards are the same.

Method. Compare the Nyquist frequency each modulation requires and the eye each produces, then note what follows.

Gen5 NRZ Nyquist	16 GHz
Gen6 at 64 GT/s with NRZ would need	32 GHz
Gen6 PAM4 symbol rate	32 GBd
Gen6 PAM4 Nyquist	16 GHz
PAM4 levels	4
Eye height relative to NRZ at equal amplitude	0.333
SNR penalty	9.542 dB
Consequence	a raw BER near 10^{-6}, so FEC becomes mandatory

How this is got wrong. By reading PAM4 as free bandwidth. It keeps the Nyquist frequency — and therefore the channel loss — unchanged, which is the whole point, and it pays 9.5 dB of eye for it. That payment forces three things into the specification at once: **forward error correction**, which adds latency; a **flit-based protocol**, because FEC needs fixed-size blocks and the old variable-length TLP framing does not provide them; and **retry at the flit level** rather than the packet level. Gen6 is therefore not an incremental speed bump but a protocol change, and any IP behind it sees different latency statistics.

Y2.2 Link training: the LTSSM as a bring-up tool

Table 473. LTSSM states a bring-up engineer actually watches

State	What it establishes	Stuck here means
Detect	A receiver is present on the far end	No far end, or AC coupling caps missing / wrong value
Polling	Bit lock and symbol lock at 2.5 GT/s	Reference clock, PHY configuration, or gross signal integrity
Configuration	Lane numbering, link width, lane reversal, polarity inversion	Lane mapping error in the board or the controller
Recovery	Speed change and equalisation	The commonest stall: the link comes up at Gen1 and will not train higher
L0	Normal operation	—
L0s / L1 / L2	Power states	Exit latency violations, or a partner that does not support the state
Hot Reset / Disabled	Explicit teardown	Software

Graduate · ‘Trains at Gen1, fails at Gen3’ is a diagnosis, not a symptom, and it is worth knowing why. Every PCIe link starts at 2.5 GT/s with no equalisation, because both ends must be able to talk before they can negotiate. The move to Gen3 and beyond runs a four-phase equalisation procedure in Recovery in which each end requests transmitter coefficient settings from the other and evaluates the result. A link that trains at Gen1 and fails above it has working wires and a failing equalisation: the channel is worse than the preset assumes, the far end's coefficient requests are being ignored or mishandled, or the receiver's evaluation is reporting success when the eye is marginal. **The debug sequence is therefore: read the link status registers for the actual speed and width; read the lane error status; capture the equalisation phase the link fails in; and only then look at the board.** Controllers that expose per-phase equalisation status are much faster to bring up, and this is a feature worth asking a vendor for.

Table 474. Unit intervals and the budgets they imply

Generation	GT/s	UI (ps)	30 % of UI (ps)	10 % of UI (ps)	Typical channel loss budget (dB)
Gen3	8	125	37.5	12.5	20
Gen4	16	62.5	18.8	6.25	20
Gen5	32	31.25	9.38	3.13	28
Gen6	64	15.63	4.69	1.56	32

The loss budgets are the figures commonly cited for the base specification's channel; they have not been checked against the current specification text in this repository, which is a paid document. The UI column is exact arithmetic.

Y2.3 Protocol overhead: from GB/s on the box to GB/s in the driver

Table 475. TLP efficiency against maximum payload size, Gen5 x16

Max payload (B)	Overhead bytes	Total bytes	TLP efficiency	× encoding efficiency	Usable GB/s
64	24	88	0.7273	0.7161	45.83
128	24	152	0.8421	0.8291	53.07
256	24	280	0.9143	0.9002	57.61
512	24	536	0.9552	0.9405	60.19
4,096	24	4,120	0.9942	0.9789	62.65

The overhead figure counts a 12-byte header, sequence number, LCRC and framing; it ignores DLLP acknowledgements and flow-control updates, which consume a further few per cent. **The lesson is the first column: a device restricted to 128-byte payloads gets roughly three quarters of the bandwidth of one that negotiates 512, and maximum payload size is negotiated to the minimum of the whole path, so one old switch in the chain sets it for everybody.**

Worked example 77. Why a DMA engine behind PCIe needs deep outstanding-read support

Given. A Gen4 x8 link, 4 μ s round-trip read latency to host memory, requesting 512-byte reads. The engine must sustain 12 GB/s.

Method. Bandwidth–delay product again, exactly as in Part X11 — the formula does not care that the wire is now a PCIe link.

Gen4 x8 usable bandwidth	15.75 GB/s
Required bandwidth	12 GB/s
Bytes in flight needed	46.88 kB
512-byte reads outstanding	94
Tag space needed (10-bit tags allow 768)	94 of 768
Completion buffer required	46.88 kB

How this is got wrong. By sizing from the link rate and ignoring the latency. A device with 32 outstanding reads on this link achieves $512 \times 32 / 4 \mu\text{s} = 4 \text{ GB/s}$ regardless of the link being capable of 15. The second trap is the completion buffer: those bytes in flight must land somewhere, so the buffer is not optional and it is tens of kilobytes. **Outstanding-transaction capability and completion-buffer size are the two numbers that decide whether a PCIe device performs**, and they belong on the first page of its datasheet, not in an appendix.

Y2.4 What the corpus contains, and what it does not

This book's code appendix includes **198,332 lines** of a working open-source PCIe datapath: DMA engines, TLP generation and parsing, and AXI bridging. It is genuinely useful and it is worth being precise about what it is. **It is the transaction and data-link layer above a vendor hard macro** — the PHY, the LTSSM, the equalisation procedure and the serialiser are not in it and cannot be, because they are analogue and foundry-specific.

Table 476. Where PCIe functionality actually comes from, and who can sell it

Layer	Implemented as	Who supplies it	Can a small design house sell this?
Serialiser, CDR, equaliser	Hard macro in a specific process	PHY vendor or foundry	No — requires analogue design and process access
PIPE interface	Defined digital interface	Boundary between the two	—
LTSSM, lane management	RTL	Controller vendor	In principle; compliance is the barrier
Data link layer: ack/nak, flow control	RTL	Controller vendor	Yes, with effort
Transaction layer, config space	RTL	Controller vendor	Yes
Application logic behind the controller	RTL	Anyone	Yes — and this is where a design house should be

Compliance is the commercial fact about PCIe. A controller that works is not a controller that can be sold: the PCI-SIG compliance programme, its test fixtures, its interoperability workshops and the membership that permits them are a substantial and recurring cost, and a customer buying a PCIe controller is buying that compliance as much as the RTL. **For a one-**

person design house the rational position is above the controller, not inside it — build the accelerator, the DMA engine, the protocol offload that sits behind a licensed controller, and let the customer bring the controller they have already qualified.

Problem. A customer asks you to quote for ‘a PCIe Gen4 endpoint with a custom accelerator’. How do you structure the quote?

Solution. Split it explicitly, and say why in the quote itself. **Item one: the accelerator** — your design, your verification, your price. **Item two: integration with a controller the customer licenses**, quoted as integration effort with the controller named, because the effort depends heavily on which one; a controller with a clean AXI-Stream application interface is a fortnight and one with an idiosyncratic interface is two months. **Item three: what you are not supplying** — the controller licence, the PHY, the compliance testing, and the driver, each listed with who you expect to provide it. A quote that silently includes the controller either loses on price to competitors who excluded it, or wins and then discovers the licence costs more than the project. **Being explicit about scope is not a weakness in a proposal; it is the clearest signal that the quoter has done this before**, and experienced buyers read it that way.

Problem. Gen6 introduced FEC. What does that do to the latency your block sees, and why can the FEC not simply be made stronger to allow a cheaper channel?

Solution. FEC operates on fixed-size flits, so the receiver must collect a whole flit before it can correct it, and the correction itself takes time. The added latency is small in absolute terms — tens of nanoseconds — but it is **added to every transaction**, and for a latency-sensitive accelerator performing fine-grained host synchronisation it can matter more than the doubled bandwidth helps. It also changes the *distribution*: retries now happen at flit granularity with a different tail than Gen5's packet-level replay. Stronger FEC is not the answer to a worse channel because latency is the constraint that a stronger code violates first: a longer code corrects more and waits longer, and PCIe's entire value proposition rests on being a low-latency load/store fabric rather than a network. **The design point was chosen to bound added latency, and the code strength followed from that bound** — not the other way round, which is the usual direction in communications and the reason PCIe's FEC looks weak to someone arriving from Ethernet.

Y3. The Ethernet MAC and Its Transceiver, Worked

The Gigabit MAC is the most-integrated communications block in existence and a good vehicle for the whole of this book: it has a datapath with hard real-time constraints, a protocol with a long tail of options, a clock-domain problem at its centre, and an interface stack whose names (GMII, RGMII, SGMII, QSGMII) encode a series of commercial compromises worth understanding.

Y3.1 Frame timing: the arithmetic that sets every buffer

Table 477. Frame times, packet rates and the inter-packet gap

Rate	Mbit/s	Min frame + preamble + IPG (ns)	Max frame + overhead (μ s)	Max frames/s (M)	IPG (ns)
10BASE-T	10	67200	1230	0.01488	9600
100BASE-TX	100	6720	123	0.1488	960
1000BASE-T	1000	672	12.3	1.488	96
2.5GBASE-T	2500	268.8	4.922	3.72	38.4
10GBASE-R	10000	67.2	1.23	14.88	9.6
25GBASE-R	25000	26.88	0.4922	37.2	3.84

Computed from 8 bytes of preamble and start delimiter, 12 bytes of inter-packet gap, and the frame itself. **The fifth column is the number that sizes the control path:** at 25 Gbit/s a new frame can start every 33 ns, so any per-frame decision — a lookup, a filter, a statistics update — must complete in that time or be pipelined.

Worked example 78. Why a MAC at 10 Gbit/s cannot process one byte per cycle

Given. 10 Gbit/s line rate. The digital logic runs at 156.25 MHz, which is the standard XGMII clock.

Method. Divide the bit rate by the clock to find the datapath width, then check what that width does to frame alignment.

Bits per clock	64
Datapath width	64 bits = 8 bytes
Bytes per clock	8
Minimum frame (64 B) in clocks	8
Can a frame start mid-word?	yes — the IPG is 12 bytes, not a multiple of 8
Alignment cases the datapath must handle	8
At 25 Gbit/s on the same clock: width	160 bits

How this is got wrong. By designing the datapath for aligned frames. Because the inter-packet gap is 12 bytes and the datapath is 8 wide, successive frames start at different byte lanes, so every parser, every CRC engine and every filter must handle all eight alignments. This is the single largest source of complexity in a wide Ethernet MAC and it is invisible in a specification that describes the protocol in bytes. **A block that assumes alignment will pass a test bench that sends one frame at a time and fail on back-to-back traffic at line rate** — which is the only traffic that matters.

Y3.2 The interface zoo, and what each trade is

Table 478. MAC-to-PHY interfaces: the same function, very different pin counts

Interface	Data bits each way	Clocking	Carries	Approx. pins
MII	4	25 MHz	100 Mbit/s	16
GMII	8	125 MHz	1 Gbit/s	24
RGMII	4	125 MHz DDR	1 Gbit/s	12
SGMII	1	625 MHz DDR serial	1 Gbit/s	4
QSGMII	1	5 Gbit/s serial	4 × 1 Gbit/s	4
XGMII	32	156.25 MHz DDR	10 Gbit/s	72
XFI / SFI	1	10.3125 Gbit/s	10 Gbit/s	4
USXGMII	1	10.3125 Gbit/s	up to 10 Gbit/s, multi-port	4

The progression is one long trade of pins against signalling difficulty. **RGMII halves GMII's pins by clocking on both edges and pays with a notorious source-synchronous timing problem:** the specification's delay requirement is met either by the board, by the PHY or by the MAC, and mismatched assumptions between the three are the most common Gigabit Ethernet bring-up failure in existence.

The RGMII delay question, stated once so it can be checked. RGMII requires the clock to be delayed relative to the data by roughly 1.5–2 ns at the receiver. That delay may be provided by a long clock trace on the board, by the PHY's internal delay (enabled by strap or register), or by the MAC's output delay. **Exactly one of the three must provide it.** Zero gives a link that does not pass traffic or passes it only at 10 Mbit/s; two gives the same symptom for the opposite reason. Because each is configured by a different party — layout, PHY firmware, RTL — nobody owns the question, and it is worth writing the answer into the integration guide of any MAC a design house ships, along with the register bits that set it.

Y3.3 64b/66b and the PCS: what the transcoding buys

Why 64b/66b replaced 8b/10b

	Step	Justification
1	8b/10b maps each byte to a 10-bit symbol chosen for DC balance and transition density.	<i>Original Gigabit encoding.</i>
2	Overhead is 25 %: a 1.25 GBd line carries 1 Gbit/s.	<i>10/8. At 10 Gbit/s that would demand 12.5 GBd, which the channel of the day could not support.</i>
3	64b/66b prefixes two bits of sync header to 64 bits of scrambled payload.	<i>Overhead 3.1 %.</i>
4	Transition density comes from a self-synchronous scrambler ($x^{58}+x^{39}+1$), not from the code.	<i>The sync header is the only guaranteed transition, which is enough for a CDR with a long time constant and would not have been enough for the receivers of 1998.</i>
5	The scrambler is self-synchronising, so a single bit error produces three errors at the descrambler.	<i>The error is fed back at the two tap positions. This multiplication is the reason the FEC above it is symbol-oriented, and it is a fact a link budget must account for.</i>

Table 479. Line-rate consequences of the encoding choice

Encoding	Expansion	Payload Gbit/s	Line GBd (NRZ)	Overhead (%)
8b/10b	1.25	1	1.25	25
64b/66b	1.0312	10	10.312	3.12

Encoding	Expansion	Payload Gbit/s	Line GBd (NRZ)	Overhead (%)
64b/66b	1.0312	25	25.781	3.12
256b/257b + RS-FEC	1.0625	50	53.125	6.25
256b/257b + RS-FEC	1.0625	100	106.25	6.25

The last two rows include the RS(544,514) FEC expansion, which is why 100 Gbit/s per lane runs at about 53.125 GBd — the number Part X4's link budget used.

Graduate · Where the design-house opportunity is in this stack. The PMA — serialiser, CDR, equaliser — is a hard macro and is not available to a soft-IP vendor. The MAC is a commodity: dozens of implementations exist, several of them open, and margins are thin. **The PCS and FEC sublayer between them is soft RTL, is algorithmically demanding, changes with every new standard, and has far fewer credible suppliers.** That combination — soft, hard, and changing — is the profile of a good product for a small house, and it is the reason this book's prior-art survey chose it. The specific opening at the time of writing is IEEE 802.3dj's concatenated FEC, where the outer RS-KP4 is well understood and the inner code and its interleaving are new.

The code appendix contains **260,596 lines** of an open-source Ethernet family, of which **29,336 lines** in 89 files are the BASE-R PCS itself — the 64b/66b encoder and decoder, the scrambler, the block synchroniser and the gearbox. Reading those files against the derivation above is the fastest way to see how a standard's prose becomes RTL.

Y3.4 Flow control, buffering and the numbers a customer checks

Table 480. Buffer needed to stop a sender in time, 100 m of copper

Rate (Gbit/s)	One-way propagation (µs)	Round trip (µs)	Bandwidth–delay product (kB)	Max-size frames in flight
1	0.5	1	0.1221	1
10	0.5	1	1.221	1
25	0.5	1	3.052	3
100	0.5	1	12.21	9

This is the buffer a receiver must have after it decides to send a PAUSE frame, because frames already in flight will arrive regardless. Add the PAUSE frame's own transmission and the partner's reaction time and the requirement grows further. **The bandwidth–delay product appears for the third time in this book**, in its third guise; it is the same formula that sized the credit buffer and the PCIe completion buffer.

Problem. A customer reports frame loss under burst traffic although your MAC reports no errors and the link is not saturated on average. Where do you look?

Solution. ‘Not saturated on average’ is the clue: averages hide bursts, and Ethernet traffic is bursty at every timescale. The sequence is: **read the drop counters and find out which stage dropped** — a MAC that cannot say whether a frame was dropped at the PHY interface, in the receive FIFO, or by the filter is much harder to defend, so this instrumentation is worth building. Then **check the receive FIFO's depth against the consumer's worst-case stall**, not its average service rate; if the consumer is a bus master, the stall is the interconnect's worst-case arbitration latency from Part X11, which is usually far longer than anyone estimated. Then **check whether flow control is enabled at both ends**, since PAUSE is negotiated and frequently disabled by default. Finally, **check the clock-rate mismatch**: two ends nominally at the same rate differ by up to 200 ppm, so a receiver without rate adaptation slowly falls behind and drops a frame every few seconds — a distinctive signature worth recognising, because the loss rate is remarkably constant.

Problem. Why does a MAC need an idle-insertion and idle-deletion mechanism at all, given that both ends are specified at the same rate?

Solution. Because ‘the same rate’ means the same nominal rate within a tolerance, typically ± 100 ppm each, so the two can differ by 200 ppm — one part in five thousand. Over a continuous stream that is one extra or missing byte every 5000, which accumulates without bound. The mechanism uses the inter-packet gap as elastic: if the local clock is slower, delete an idle byte from the gap; if faster, insert one. The gap can be shortened to a floor (five bytes in the 10 Gbit/s specifications, from twelve) which is what limits how much rate difference can be absorbed. **The consequence for a design is that the IPG a MAC sees on receive is not the IPG the far end transmitted**, so any logic that assumes twelve bytes is wrong, and any logic that uses IPG timing to infer anything about the far end is wrong twice. This elasticity, and its floor, is also why the FEC and PCS layers above must tolerate the alignment markers that periodically consume the same budget.

Y4. A Verification Agent That Runs While You Sleep

A one-person design house has one engineer and twenty-four hours in a day, and the engineer needs some of them. The only way the arithmetic works is for verification to run unattended overnight and to leave behind something better than a log file. This part documents such a system, which lives in this repository under `edu/agent/` and which is exercised by `tests/test_verif_agent.py`. It is deliberately small — roughly the size one person can maintain — and it is deliberately suspicious of itself.

Figure 62. One iteration of the loop. The first box is the one most regression systems lack, and it is the reason the rest can be believed.

Y4.1 The design, and the two failures it is built around

An unattended regression can fail in two directions, and the second is far more dangerous than the first. It can report a failure that is not there, which wastes a morning. Or it can report success while checking nothing, which wastes a tape-out. The loop is structured so that the second is caught by construction.

Table 481. What each stage is for, and what would go wrong without it

Stage	What it does	Without it
Self-check	Corrupts one golden value and asserts that the comparison notices	A comparison that silently stopped comparing reports green forever. This is the failure mode this whole repository is organised against
Regression	Runs the DUT and the golden model on the same stimulus and compares every output	—
Distinct-output count	Counts how many <i>different</i> values the golden model produced	A stimulus that drives one constant passes trivially. The loop treats fewer than two distinct outputs as a failure, not a pass
Shrink	Re-runs the single failing stimulus on its own	A 4000-transaction failure report that nobody can debug
Repair search	Generates single-edit candidates from a rule library and tests each	The engineer starts every morning from a raw failure
Three gates	Original seed, an unused seed, and the self-check	An edit that special-cases the failing input passes. The overfitting gate is the reason this can be left running unattended

Graduate · The overfitting gate deserves its own sentence, because automated repair without it is actively harmful. A search that accepts any edit making the failing test pass will, given a large enough rule library, eventually find one that hard-codes the answer. Such an edit is worse than the original bug; the bug was visible and the patch is not. The rule here is that a candidate must pass a seed that was *never used during the search*, which is the same train/test separation that any honest em-

irical claim requires. This book's Part X8 makes the same point about a bug-find-rate curve, and Part X1 about a range justified by simulation: **a number validated on the data that produced it is not validated.**

Y4.2 The blocks under test, measured now

Table 482. The agent's blocks, run at build time against their golden models

Block	Golden model	Stimuli	Mismatches	Distinct outputs	Checker bites?	Wall time
crc32_8	Python's <code>zlib.crc32</code>	1,500	0	1,499	yes	0.0352 s
crc32_stream	—	52	0	51	yes	0.0406 s
gf_mul	the repository's <code>gf.py</code>	1,500	0	808	yes	0.0303 s
regfile	—	1,500	0	169	yes	0.0428 s
rs_syn_step	the repository's <code>gf.py</code>	1,500	0	796	yes	0.0309 s

Run by this chapter as the book is rendered, with Icarus Verilog. The 'distinct outputs' column is the one that makes the 'mismatches' column mean something; a zero in the fourth column beside a one in the fifth would be a false green.

Undergraduate review · Why the CRC block's golden model is `zlib` and not a hand-written CRC. If the reference and the design are written by the same person from the same understanding, they share that person's misunderstandings, and the comparison certifies the misunderstanding rather than detecting it. This is not hypothetical: reflected versus non-reflected CRC, initial value, and final XOR are four independent conventions and a hand-written reference gets at least one of them wrong about as often as the RTL does. **An independent reference is worth more than a more accurate one.** The same argument is why a modelling team is organisationally separate from the design team — the independence is the product.

Y4.3 Repair, measured on injected faults

The claim that the agent repairs Verilog is only worth making with numbers behind it. The following table injects known faults into the GF multiplier and reports what the search did, computed while this page was rendered.

Table 483. Injected faults and what the repair search did, run at build time

Injected fault	Mismatches before	Candidates tried	Rule that repaired it	Rejected for overfitting	Search time
overflow bit read one position low	393 / 400	7 of 7	MSB 인덱스 M-2 / M-1	0	10.2 s
accumulate with OR instead of XOR	384 / 400	3 of 7	OR / XOR	0	0.0793 s
reduction shift in the wrong direction	390 / 400	5 of 7	우시프트 / 좌시프트	0	0.114 s

The search is exhaustive over single edits from the rule library, so a 'not repaired' result means the fault is outside the library — which is information, not a failure. The candidate counts are small because the rule library is deliberately narrow; a library that edits anything would find something for every fault and most of it would be wrong.

What this system is not. It is not a bug finder for logic it has no golden model of, and it is not a substitute for a verification plan. The rule library covers the small syntactic faults that a tired engineer introduces at two in the morning — an inverted comparison, a shift the wrong way, an index off by one — and nothing else. A missing state in a state machine, a protocol rule that was never implemented, or a specification misread will all pass the repair search untouched, because there is no single-token edit that fixes them. **The value is not that it repairs everything; it is that it removes the trivial failures from the morning's queue,** with a patch and a minimal reproducer attached to each of the rest.

Y4.4 Running it for twenty-four hours

The launcher follows this repository's rule for background work, which exists because the obvious way does not work: a process started with a bare & from inside an agent session is reaped when that session's process exits, and the evidence for that is a night in which nothing ran and a message the next morning saying it had.

```
edu/agent/run.sh - the launcher
#!/usr/bin/env bash
# 24시간 회귀 에이전트를 **부모가 죽어도 사는** 방식으로 띄운다.
#
# CLAUDE.md 의 백그라운드 규칙 그대로: setuid + nohup + disown, 그리고
# stdin/stdout/stderr 를 전부 리다이렉트한다. claude -p 가 응답 직후 끝나도
# 이 프로세스는 남는다.
#
# 사용:  bash run.sh [--적용] [시간]
#
# 확인은 `ps -p $!` 가 아니라 `pgrep -af agent.py` 로 한다 -- setuid 가 fork 하므로
# $! 는 이미 끝난 래퍼다. 셸 변수명에 한글을 쓰지 않는다 (bash 는 받지 않는다).
set -u

HERE="$(cd "$(dirname "$0")" && pwd)"
LOGDIR="${SE_AGENT_LOG:-/home/user/SE/logs}"
mkdir -p "$LOGDIR"
LOG="$LOGDIR/verif_agent.log"

APPLY=""
HOURS="24"
for a in "$@"; do
  case "$a" in
    --적용|--apply) APPLY="--적용" ;;
    *) HOURS="$a" ;;
  esac
done

setuid nohup python3 "$HERE/agent.py" --시간 "$HOURS" ${APPLY:+$APPLY} \
  > "$LOG" 2>&1 < /dev/null &
disown

sleep 3
if pgrep -af "agent.py" > /dev/null; then
  echo "살아 있다:"
  pgrep -af "agent.py"
  echo "로그: $LOG"
  sleep 2
  echo "--- 로그 첫 줄 ---"
  head -3 "$LOG"
else
  echo "띄우지 못했다. 로그:"
  cat "$LOG"
  exit 1
fi
```

Table 484. The three things that make an unattended launch survive

Element	What it detaches from	What happens without it
setuid	The parent's session and process group	The process dies with the session that started it
nohup	SIGHUP	The process dies when the terminal closes
disown	The shell's job table	The shell may still signal it on exit

Element	What it detaches from	What happens without it
< /dev/null and redirected output	The terminal's pipes	A write to a closed pipe kills the process, often hours later
pgrep -af agent.py	—	ps -p \$! reports nothing even when the job is running, because setsid forks when it is already a group leader, so \$! is the wrapper that has already exited. Believing it leads to starting a second copy that overwrites the first one's files

Do not put non-ASCII text in a pgrep -f pattern. The pattern is matched against /proc/<pid>/cmdline, whose bytes may not decode in the current locale; a pattern containing characters that cannot be decoded matches nothing, and a match of nothing reads as ‘finished’. A job that is running is then reported as done, or started a second time. Wait on a **PID** with kill -0, or match an ASCII-only fragment of the command line.

Worked example 79. What a night actually buys

Given. The loop measured above runs roughly 900–2000 regression rounds per minute on this container for these small combinational blocks, each round a fresh seed.

Method. Extrapolate to eight hours and compare with what a person can supervise. Then note the limit, which is not the compute.

Rounds per hour (order of magnitude)	10 ⁵
Rounds in an eight-hour night	≈10 ⁶
Distinct seeds consumed	one per block per round
Engineer-hours consumed	0
What limits the value	the golden models and the stimulus, not the machine

How this is got wrong. By reading the round count as coverage. A million rounds of the same random distribution explore the same region a thousand times. Part X8's coupon-collector arithmetic says where the return flattens, and the answer is far below a million for any of these blocks. **The honest use of an overnight run is not volume but variety:** rotate the constraint sets, inject faults deliberately to measure whether the suite still bites, and re-run the previous night's minimal reproducers as a growing regression. A loop that only turns the seed is a loop that stops learning after the first hour.

Problem. You arrive in the morning to nine failures, all in one block, all with the same minimal reproducer shape. What do you do first?

Solution. Deduplicate before debugging. Nine reports with one shape are one bug, and the first task is to confirm that by checking whether a single edit makes all nine reproducers pass — which the repair search has already attempted and logged. If it found an edit and the overfitting gate rejected it, **that rejection is the most informative line in the whole night's ledger:** it says a plausible local fix exists and is wrong, which usually means the bug is one level up from where it manifests. If the search found nothing, read the minimal reproducer and ask which of the four X8 categories it belongs to before opening the RTL. The failure the agent cannot repair is the one worth your morning; the ones it repaired are worth only a review of the patch.

Problem. Your manager asks whether the agent could write the RTL as well as fix it. What is the honest answer?

Solution. The honest answer distinguishes two things this chapter has kept separate. **Search over a small edit space with a strong oracle is reliable**, and that is what this agent does: the golden model is the oracle, the edit space is a dozen rules, and the three gates bound the false-accept rate. **Generation without an oracle is not**, because nothing is checking the result except a human reading it, and the failure mode is code that looks right. The useful framing for a design house is therefore: let generation propose and let the oracle dispose, and **invest in the oracle**. A team with an excellent golden model and a mediocre generator will out-ship a team with the reverse, because the first can accept help from any source and the second cannot tell good help from bad. That is also why the modelling role — the one this book is written for — becomes more valuable as generation improves, not less.

Y5. The Commercial Mechanics of Selling an IP Block

A design house that cannot price, license and support its work does not have a business, it has a hobby with good documentation. This part gives the arithmetic of the commercial side with the same seriousness as the technical parts, because the failure modes are just as specific and rather less discussed.

Y5.1 The three revenue models and when each applies

Table 485. How semiconductor IP is actually sold

Model	Customer pays	Suits	Risk to you	Risk to them
Licence royalty +	A licence fee, then a per-unit royalty	High volume, standard function	Royalty depends on their success and their honesty — audit rights matter	Ongoing cost; they will try to convert it to a buyout
Paid-up / perpetual licence	One fee, unlimited units	Customers who cannot tolerate per-unit accounting	You capture none of their upside	Large up-front commitment
Services NRE /	Engineering time	Where a one-person house should start	No leverage — you are paid once for each hour	Low; they own the result
Subscription	Annual fee for access and updates	Rapidly changing standards	Churn	Dependence on your survival
Open core + support	Support and customisation	Building reputation from nothing	Hard to monetise	Very low

Worked example 80. When a royalty beats a buyout, from the customer's side

Given. A block licensed at \$150 000 plus \$0.20 per unit, or \$600 000 paid up. The customer's forecast is 1 million units over three years, but forecasts in this market are routinely out by 3× in both directions.

Method. Compute the break-even volume, then compute what each party's exposure is above and below it. The break-even is arithmetic; the interesting part is the asymmetry around it.

Break-even volume	2,250,000
Royalty model cost at 1M units	3.5000×10^5 USD
Buyout cost	600,000 USD
Royalty cost at 0.3M units (forecast ÷ 3)	2.1000×10^5 USD
Royalty cost at 3M units	7.5000×10^5 USD
Your revenue at 3M units under buyout	600,000 USD
Your revenue at 3M units under royalty	7.5000×10^5 USD

How this is got wrong. By negotiating the break-even and not the distribution. Both parties can compute 2.25 million units; what decides the deal is who is more confident and who can bear the downside. A one-person house with no cash reserve should prefer the larger up-front fee even at a worse expected value, because **surviving to the next contract dominates expected value when a single bad quarter ends the business**. The standard compromise is a royalty with a cap and a floor, which bounds both parties' exposure and is easier to agree than either extreme.

Y5.2 What a customer actually receives

Table 486. The delivery package, item by item

Item	Form	Why it is not optional
RTL	Encrypted or plain System-Verilog	The product — but the smallest part of the package
Testbench and tests	UVM or equivalent, runnable	The customer must be able to re-verify after editing; without it your block becomes untouchable and therefore unusable
Reference model	C or C++, bit-accurate	Their system model needs it; also it is what makes your claims checkable
Synthesis scripts and constraints	SDC plus a script	Timing closure in <i>their</i> flow is where integrations fail
Lint and CDC waivers	Files with justifications	Their sign-off will run these tools; unexplained violations stop the project
IP-XACT / integration metadata	XML	Automated integration; increasingly a purchase requirement
Register map	Generated from one source	Hand-maintained duplicates diverge, and the divergence is discovered by software at the worst time
Documentation	Datasheet, integration guide, release notes	Support cost is inversely proportional to documentation quality
Known-issue list	A document	Omitting it does not remove the issues, it removes your credibility when they are found

Graduate · The known-issue list is the item that distinguishes a professional supplier, and it is counter-intuitive to first-time vendors. Every block has limitations: a configuration that was never verified, a corner that fails a lint rule for a defensible reason, a performance figure that holds only above a certain clock ratio. A customer who finds these themselves concludes you did not know; a customer who reads them in your release notes concludes you did. **The second customer calls you when they have a problem instead of calling your competitor.** Write the list, keep it honest, and put dates and work-arounds beside each entry.

Y5.3 Support: the cost nobody budgets

Table 487. Support load against customer count, at 1.5 engineer-hours per query

Customers	Queries per customer per year	Queries per year	Engineer-hours	% of a person-year (1800 h)	Working weeks
1	40	40	60	3.33	1.5
3	30	90	135	7.5	3.38
5	25	125	187.5	10.4	4.69
10	20	200	300	16.7	7.5
20	18	360	540	30	13.5

Queries per customer fall with experience because the documentation improves and the frequent questions get answered in it. **At twenty customers support is a full-time job**, which for a one-person house means either hiring, raising prices to slow growth, or investing hard in documentation and self-service — and the third is the only one available immediately.

Worked example 81. Pricing that accounts for support

Given. You expect 8 customers over three years for a block that took 44 weeks to build. Target: recover the build and support and earn a living. Your cost of living plus overhead is \$120 000 a year.

Method. Total the engineering, add the support from the table above, and divide. Then compare with what the market will bear, because the two are independent numbers and the smaller one wins.

Build effort	44 weeks
Support over 3 years at 8 customers	19.8 weeks
Total effort	63.8 weeks
Cost at \$120k/year	1.4723×10^5 USD
Break-even price per customer	18404 USD
With a 40 % margin	30673 USD
If only 3 customers materialise	65929 USD

How this is got wrong. By pricing from cost and ignoring the market. The last row is the real risk: with three customers instead of eight, the price that covers cost is more than double, and there is no reason a customer will pay it. The standard mitigations are to **start with services revenue**, which is paid whether or not the block sells; to **sell the first block below cost to a reference customer** in exchange for a public reference, which is worth more than the margin; and to **build blocks whose adjacent variants share most of the effort**, so the second customer in a family costs a fraction of the first.

Y5.4 Legal and quality items that bite a small vendor

Table 488. Contractual terms and what each one means in practice

Term	What the customer wants	What you should watch
Indemnification	You cover patent claims against the block	Cap it at fees received. Uncapped indemnity can exceed the company's value; it is the single most dangerous clause for a small vendor
Warranty	The block conforms to the specification	Define the specification precisely and tie the warranty to it, not to 'fitness for purpose'
Escrow	Source held by a third party in case you disappear	Reasonable; budget the fee and keep the deposit current
Acceptance criteria	A defined test they run	Insist the criteria be written and runnable before delivery. Undefined acceptance is an unbounded obligation
Exclusivity	Nobody else gets the block	Price it as the lost market, and time-limit it
Support term	Years of updates	Define what an update is; a new standard revision is a new product

Provenance of the source you ship is a hard requirement, not a formality. If any part of your block derives from code with a copyleft licence, or from a previous employer's work, or from a reference design with redistribution limits, a customer's legal review will find it — they scan for this — and the deal ends there. Keep a per-file record of origin, do not paste from sources you cannot name, and be able to produce that record on request. **The code appendix of this book is an illustration of the standard:** every file reproduced in it is named with its repository and its line count, and a reader can trace any line back to its source.

Problem. A prospective customer asks for a three-month free evaluation with full source. How do you respond?

Solution. Not with a flat refusal, and not with the source. The request is reasonable in intent — they cannot buy what they cannot assess — and unreasonable in form, because full source for three months is the product. The standard structures, in increasing order of what you give away: an **evaluation package** of documentation, the datasheet, the register map and simulation results, which costs you nothing and answers most questions; an **encrypted or obfuscated netlist or FPGA bitstream** they can integrate and measure but not read, which answers the performance question; and a **paid evaluation licence** whose fee is credited against the full licence if they proceed, which aligns both parties and filters out tyre-kickers at no cost to a serious buyer. **The paid evaluation is the one to propose;** a customer who will not pay a small fee to evaluate is very unlikely to pay a large one to license.

Problem. Your block has been shipping for a year when a customer reports a bug that affects every unit they have built. What do you do, in order?

Solution. Reproduce it before saying anything about cause. Ask for the configuration, the stimulus and the failing condition, and reproduce it in your own environment; a report is a hypothesis. **Then determine the blast radius** — which configurations, which versions, which other customers — because the answer determines whether this is one email or a notification to everyone. **Then notify affected customers before they find it**, with what is known, what is not, and when the next update will come; a vendor who reports their own bug keeps the account, and one who is caught concealing it does not. **Then fix, with a regression test that would have caught it**, and say in the release notes what that test is. **Finally, ask why the verification plan missed it** and fix the plan, not just the code — Part X8's mutation argument applies directly: if the suite did not catch this, inject it and find out what else of the same shape it would miss.

Y6. From a Paper to a Block, and Back to a Paper

Research papers are the cheapest source of architecture a design house has, and the most dangerous, because a paper's incentives are not a product's incentives. A paper must be novel; a product must be robust. A paper reports the configuration that worked; a product must survive the ones that did not. This part is a procedure for extracting value from the literature without inheriting its optimism — and, in its second half, for publishing without committing the same offence.

Y6.1 Reading a hardware paper in the order that matters

Table 489. What to read, in order, and what you are looking for

Read	You are asking	Stop if
The results table	What was actually measured, in what units, against what baseline	The baseline is the authors' own strawman rather than a published comparable
The methodology section	Simulated, synthesised, or fabricated? At what node? Post-layout or post-synthesis?	Post-synthesis numbers compared against someone else's post-layout numbers — a 20–40 % difference presented as a contribution
The assumptions	What is held fixed, and is it fixed in your application?	The gain depends on a parameter your customer sets differently
The limitations paragraph	What do the authors admit?	There is not one
The related work	Who else did this, and how does this compare?	It is a list of citations rather than a comparison
The algorithm	Can you implement it from the text alone?	Only now — reading the algorithm first is how a fortnight disappears

The recurring pattern in hardware papers is the unstated operating point. A result is reported at the configuration where the proposed technique wins, and the sweep that shows where it loses is absent. This is not usually dishonesty; it is page limits and the reviewing process. But it means **the first thing to do with a promising technique is to reproduce the sweep the paper did not print**, in your own model, and find the crossover. If the crossover is on the wrong side of your customer's operating point, the technique is a publication and not a product — and you have learned that in a week rather than a quarter. This repository's own record contains the mirror image of this mistake: a headline figure of '1/59 the area' taken from the most favourable corner of a sweep, with the loss condition present elsewhere in the same document.

Worked example 82. Reproducing the missing sweep: a worked reading

Given. A paper claims an unrolled architecture removes a timing bottleneck and reports a 59× area advantage over the standard-cell baseline at one operating point.

Method. Identify the parameter the advantage depends on, sweep it, and find where the sign changes. Here the parameter is the number of taps that must be unrolled, which grows with channel loss; area grows as 2^n .

Claimed advantage at the reported point	59×
Unrolled taps at that point	2
Area factor at $n=2$	4
Unrolled taps at a realistic 30 dB channel	5
Area factor at $n=5$	32
Advantage rescaled	7.38×
Taps at which the advantage disappears	7.88

How this is got wrong. By quoting the headline and moving on. The arithmetic above takes ten minutes and changes the conclusion from ‘adopt’ to ‘adopt for short channels only’, which is a completely different product decision. The general procedure is: **find the exponential, and find where it eats the constant.** Almost every architecture paper contains exactly one such exponential, and the paper's operating point is chosen just below where it bites.

Y6.2 The prior-art search, done so that it means something

This book's repository enforces a rule that a prior-art note must be committed before the code for a topic. The rule exists because the same failure occurred five times: choose a topic, build, measure, write, and only then discover the work already existed. The procedure below is what the rule requires.

Table 490. A prior-art note that is worth the time it takes

Section	Content	The failure it prevents
Closest prior work	arXiv or DOI, year, and one sentence on what it did	‘I could not find anything’, which is not a finding
How we differ	One paragraph, specific, falsifiable	A difference that evaporates under a reviewer's first question
Queries run	The literal search strings, at least three, with the databases	An unrepeatable search
Where you have not looked	Named: patents, a paywalled venue, a language, an industry body's documents	Treating absence of evidence as evidence of absence
Confidence of each citation	Full text, abstract, listing, or snippet	Citing something you have not read as though you had
Possibilities not yet eliminated	A list	A false sense of completion

Graduate · **The confidence marker is the mechanically enforceable part and therefore the part worth automating.** This repository requires every citation in a paper to carry, on the document's face, whether the author read the full text, the abstract, a listing entry, or only a search snippet; a gate checks the document against a ledger of citations and fails the build if they disagree. What the gate *cannot* check is whether the marker is honest, and the repository's notes say so explicitly. **That is**

the correct division: the machine forces the claim to be stated, and a human is accountable for its truth. A process that pretends the machine can verify reading is worse than one that admits it cannot, because it invites everyone to stop looking.

Problem. You find a patent that appears to cover the architecture you were about to build. What are the possible responses, and which are realistic for a one-person house?

Solution. Six responses exist and only some are realistic. **Design around:** read the *claims*, not the abstract — the claims are the legal scope and are usually much narrower than the description — and find an element of the independent claim you can avoid. This is the normal answer and it is realistic. **Check the status:** the patent may have lapsed for unpaid maintenance fees, may never have been granted in your customers' jurisdictions, or may expire before your product ships; all are cheap to check and all are common. **License it:** realistic only if the holder licenses, which large semiconductor holders often do not to small parties. **Challenge validity:** not realistic — the cost exceeds a small house's annual revenue. **Ignore it:** not an option; wilful infringement carries enhanced damages, and your customer's legal review will find it anyway. **Change topic:** often the correct answer, and the reason the prior-art search comes first. **The meta-point is that the patent is information, not a verdict,** and reading the claims carefully is a skill worth acquiring because it converts a project-ending discovery into a design constraint about half the time.

Y6.3 Measuring so that the number survives a reviewer

The four rules below are this repository's response to four specific measurements that were reported and were wrong. They are stated as a checklist because each failure looked, at the time, like a result.

Table 491. Four checks before a number is said aloud

Check	What went wrong without it	How to do it
Did you measure the quantity you defined?	A tool reported the longest path in the whole netlist; the quantity wanted was the longest path <i>around a loop</i> . Different number, same units	Isolate the quantity — cut the loop, build the combinational equivalent, and measure that
Is the operating point healthy?	A residual analysis was run at a point where the bit error rate was 0.49 — the link was not working, so every derived number was noise	Sweep first, find a working point, then measure. Report the point
Is there an independent cross-check?	A reconstruction double-counted a term; the error was invisible until the same quantity was computed a second way	Closed form, a second estimator, or a hand calculation — and print the difference
Have you killed the trivial explanations?	'Seven gates, zero mismatch' — because at that operating point the equalizer taps were near zero and the loop was doing nothing	Write the list of boring reasons the number could look good, then measure each one away

If you cannot do all four, say which one you could not do. A number with a stated gap is usable by a reader, who can weigh it. A number presented as complete when it is not is a claim the reader cannot calibrate, and when it turns out to be wrong it costs more than the information was ever worth. This applies with full force inside a company: the colleague reading your slide has no way to know which checks you ran unless you say.

Problem. Your simulation shows a $3\times$ improvement. What do you do before telling anyone?

Solution. Assume it is a bug, because at that magnitude it usually is, and spend an hour trying to prove it. **Check the baseline actually runs:** the commonest cause of a large speed-up is a baseline that is mis-configured, unoptimised, or silently failing, and comparing against a broken baseline is the strawman failure from Y6.1 committed against yourself. **Check the units and the normalisation** — per operation, per cycle, per joule and per second are four different claims. **Check that both sides did the same work:** a fast path that skips a case the baseline handles is not faster. **Compute the improvement a second way,** from first principles, and see whether $3\times$ is even plausible given what changed; if the change removed 20 % of the operations, a $3\times$ speed-up needs an explanation beyond the operation count. **Only then look for the mechanism,** and when you report it, report the mechanism rather than the multiplier — a number with an explanation survives scrutiny and a number without one does not.

Problem. Should a one-person design house publish at all?

Solution. Yes, and for reasons that are commercial rather than academic. A publication is **evidence a customer can check** before trusting a supplier they have never heard of, which is the central problem of a new house. It is **defensive prior art:** published material cannot later be patented against you, which is cheap insurance compared with a patent of your own. It **forces the four checks above,** because a reviewer will ask, and work that survives review is work you can quote in a datasheet. And it **brings the people** — collaborators, customers and the occasional acquirer read the literature of their field. The cost is real: a paper is several weeks, and a rejection is several more. The pragmatic compromise many small houses take is an arXiv preprint plus a workshop or industry conference talk, which captures most of the benefit at a fraction of the cost of a top-tier submission, and **which is perfectly compatible with holding back the implementation details that are actually the product.**

Y7. Debug and Bring-Up, With the Arithmetic

Bring-up is the phase in which the difference between engineers is largest, and most of that difference is method rather than knowledge. The method is binary search over hypotheses, executed with discipline, and it can be made quantitative: each observation should halve the space of possible causes, and an observation that does not is a waste of an afternoon.

Y7.1 Debugging as information gain

Why the right measurement is the one that splits the space evenly

	Step	Justification
1	Let there be N plausible causes, each with prior probability p_j .	<i>The hypothesis space after reading the symptom.</i>
2	A test partitions the space: outcome A is consistent with a subset, outcome B with the rest.	<i>Any observation does this, well or badly.</i>
3	The information gained is the entropy reduction, maximised when the two subsets have equal probability mass.	Not equal count — equal probability. <i>Splitting off one unlikely cause teaches almost nothing.</i>
4	k ideal tests reduce N equiprobable causes to $N/2^k$.	<i>So twenty causes need about five tests, not twenty.</i>
5	A test whose outcome you can predict has zero information.	<i>If you are confident what will happen, do not run it. This single rule eliminates most wasted bring-up time.</i>

Table 492. Tests needed under binary search versus one-at-a-time elimination

Plausible causes	Ideal tests ($\log_2$)	One-at-a-time, worst case	One-at-a-time, average	Ideal as % of worst case
4	2	4	2	50
8	3	8	4	37.5
16	4	16	8	25
32	5	32	16	15.6
64	6	64	32	9.38

A bring-up with 32 plausible causes is five good measurements or thirty-two bad ones. **The whole skill is in choosing tests that split the space rather than tests that confirm a favourite hypothesis.**

Graduate · **The favourite-hypothesis trap has a specific signature.** An engineer who believes the problem is in module X runs tests that would be consistent with X, gets results consistent with X, and becomes more confident — while every one of those tests was also consistent with Y and Z. The discipline that prevents it is to **write down what each outcome would rule out before running the test**. If the answer is ‘nothing, either way’, the test is confirmation and not evidence. This is the same rule as the verification one in Part X8: a test that no broken implementation would fail is not a test.

Y7.2 The bring-up sequence, in dependency order

Table 493. Bring up in this order, because each step depends on the previous

Step	Check	If it fails
1. Power	Every rail at the right voltage, in the right sequence, with the ripple in spec	Nothing above this means anything. Sequence violations can damage parts

Step	Check	If it fails
2. Clocks	Every clock present, at the right frequency, with acceptable jitter	Measure at the die if possible; a clock present at the oscillator is not a clock present at the block
3. Reset	Asserted long enough, released cleanly and synchronously	The most common silent failure — a block that half-resets produces a state that no simulation ever visited
4. Register access	Read an ID register; write and read back a scratch register	If this fails, everything above is suspect; if it works, the bus, clock, reset and power are all proven at once
5. Static configuration	Program the block; read back every register	Read-back mismatch localises to the register file immediately
6. Loopback	Internal loopback first, then external	Separates the block from the channel — the single most valuable feature to design in
7. One transaction	One packet, one frame, one transfer	Debuggable; a stream is not
8. Line rate	Continuous traffic	Reveals everything the single transaction hid: buffering, back pressure, rate adaptation, alignment
9. Corner conditions	Temperature, voltage, rate extremes	Where the margin problems live

Step 4 is worth more than its position suggests. A readable identification register with a known constant value proves, in one transaction, that the supply is up, the clock is running, the reset released, the bus is connected, the address decode is right and the endianness matches. There is no other single test with that much power, and providing one costs a design a dozen gates. **An IP block without an ID register and a scratch register is harder to bring up by a factor that is hard to overstate**, and their absence is a reasonable reason for a customer to choose a competitor.

Worked example 83. Why internal loopback pays for itself in one bring-up

Given. A SerDes-attached block fails to pass traffic. Without loopback there are, say, 24 plausible causes spanning the transmitter, the channel, the connector, the far end and the receiver. Internal loopback splits them into 'inside the chip' and 'outside'.

Method. Apply the information argument: count the tests needed with and without the feature, at roughly two hours per test including setup.

Plausible causes	24
Ideal tests without loopback	5
Causes remaining after a loopback result	12
Ideal tests after loopback	5
Hours saved if each test costs 2 h	0
But: tests without loopback are <i>not</i> even splits	this is the real saving
Realistic sequence without loopback	10–15 tests, several requiring board rework
Realistic sequence with loopback	4–6 tests, none requiring rework

How this is got wrong. By counting only the ideal test count, which barely changes. The value of loopback is not that it reduces $\log_2 N$ by one; it is that **without it, no available test splits the space evenly** — every measurement is at one end of the chain and rules out little. A feature that creates an even split where none existed is worth far more than its effect on the count suggests. The same argument justifies per-stage error counters, snapshot registers and a pattern generator: each one manufactures a clean partition of the hypothesis space.

Y7.3 Reading a symptom

Table 494. Symptom to first hypothesis

Symptom	Most likely class	The distinguishing test
Works at low rate, fails at high rate	Timing or bandwidth	Vary the rate and find the exact threshold; a sharp threshold means timing, a gradual one means buffering
Fails after a fixed time, always the same	A counter wrapping, or a buffer filling	Compute what wraps in that time at that rate — the arithmetic usually names the register
Fails randomly, low rate of failure	Metastability, marginal timing, or a rare data pattern	Vary temperature and voltage: timing moves, a data pattern does not
Works in simulation, fails in silicon	Something not modelled	Reset, clock, power, X-propagation, or an unmodelled analogue behaviour. List what the simulation did not contain
Fails only with a specific partner	Interoperability	Capture the link and compare against the specification, not against your other partner
First transaction after idle fails	A power or clock state exit	Disable the low-power state and see if it disappears
Corrupt data with a regular period	Rate mismatch or an alignment marker	Compute the period in symbols and compare with the marker interval

Problem. A link passes traffic for exactly 71 minutes and then drops a frame, reliably. What wraps in 71 minutes?

Solution. Do the arithmetic rather than guessing. At 1 Gbit/s and 8 bits per byte a byte counter increments 125 million times a second; 71 minutes is about 4260 s, giving roughly 5.3×10^{11} bytes — close to 2^{39} . At a 156.25 MHz clock, 4260 s is about 6.7×10^{11} cycles, near $2^{39.3}$. So look for a counter of about 39 or 40 bits — a 40-bit statistics counter, or a timestamp. **The technique generalises: convert the failure period into counts of every periodic event in the system and see which lands on a power of two.** It also works for suspiciously round numbers in other bases: 71 minutes is not obviously special, which is exactly why the conversion is necessary. A failure at 49.7 days would be a 32-bit millisecond counter and is recognisable on sight; the same reasoning found it.

Problem. Silicon fails a case that simulation passes. Where do you look first, and what does that tell you about your verification plan?

Solution. Look at the list of things the simulation did not model, because that is where the answer is by definition. The usual entries: **reset** — simulation often starts from an initialised state that silicon never has, so an uninitialised register that simulation reads as a known value reads as garbage in silicon; **X-propagation** — a simulator's optimistic X handling can let an unknown resolve to a definite value through a multiplexer, hiding exactly this class of bug, which is why X-pessimistic or four-state gate-level simulation exists; **clock and power sequencing**, rarely modelled at all; **analogue behaviour**, from supply droop to the settling of an off-chip device; and **real timing**, since RTL simulation is untimed. What this says about the plan is concrete: each of these has a known mitigation — randomised reset values, X-pessimistic simulation, gate-level simulation with back-annotated timing, and a modelled power sequence — and **the plan should name which ones it uses and which it consciously declines**. A plan that does not mention them has not declined them; it has forgotten them, and the difference shows up here.

Y8. The One-Person Path from Model to Product

The three-team structure of a large company — design, modelling, verification — exists because independence catches bugs. A single engineer cannot have organisational independence, so it has to be manufactured by process: the golden model is written before the RTL, from the specification rather than from the design, and it is never modified to agree with the RTL. This part is the procedure, with the realistic schedule and the places it goes wrong.

Figure 63. The solo flow. The dashed line is the one that matters: the golden model is the reference for every stage below it, which is what replaces organisational independence.

Y8.1 The rule that replaces a second engineer

Table 495. How to be your own independent checker

Rule	Why	What breaks without it
Write the model before the RTL	The model then encodes your reading of the specification, not your design	The model inherits the design's misunderstanding and certifies it
Never edit the model to match the RTL	A disagreement is information; resolving it by editing destroys the information	The commonest single failure of solo verification — and it feels productive while you do it
Resolve every disagreement by returning to the specification	One of the two is wrong and the text says which	You pick the one that is less work to change
Use a third source where one exists	zlib, a reference implementation, a vendor model, published vectors	Two of your own artefacts agreeing proves only that you are consistent
Write the test before the fix	Otherwise the fix is unverified and may be wrong	Regressions reappear

Rule	Why	What breaks without it
Record why each parameter has its value	You will not remember in six months, and a customer will ask	Undocumented constants become unchangeable

‘I will fix the model later’ is the moment a solo project loses its verification. When the RTL and the model disagree and the deadline is close, editing the model makes the test pass in minutes and investigating takes hours. Every such edit removes one independent check permanently, and they are not recoverable later because nobody remembers which ones were principled. The practical defence is mechanical: **keep the model in a separate commit history and require a written reason in the commit message for any change to it after the RTL exists.** The friction is the point.

Y8.2 A realistic schedule, with the failure points marked

Table 496. A 39-week single-engineer plan for a medium protocol block

Stage	Weeks	Cumulative	Where it goes wrong
Specification study and requirements	3	3	Under-reading the standard; the parameters you assume are the ones that fail interoperability
Golden model in C++ or Python	3	6	Modelling what you intend to build rather than what the spec says
Architecture study and word lengths	2	8	Choosing uniform word lengths — Part X1's sweep exists for this
RTL, first pass	5	13	Writing before the architecture is settled
Testbench and checkers	4	17	Checkers that cannot fail; run mutation testing here
Random and directed regression	5	22	Believing a flat find rate; Part X8's recovery test
Lint, CDC, synthesis	2	24	Discovering a CDC problem that needs an architecture change
Timing closure at target	2	26	Finding that the target was never achievable — check in week 2, not week 24
FPGA prototype and bring-up	4	30	No loopback or ID register — Part Y7
Documentation and packaging	3	33	Leaving it to the end, when the details are forgotten
Buffer for the unforeseen	6	39	Omitting it

The buffer is 15 % of the total and it is the row most often deleted by someone who wants the number smaller. A plan without a buffer is not an optimistic plan, it is a plan that has already failed, because the unforeseen is the only certainty in the list.

Worked example 84. What the schedule implies about what you can build

Given. 39 weeks for one block, a working year of 46 weeks, and a need to spend some of it selling and supporting.

Method. Compute how many blocks a single engineer can produce and what that means for the product strategy.

Weeks per block	39
Working weeks per year	46
Weeks available for sales and support	7
Blocks per year	1.18
Blocks in three years, ignoring support growth	3.54
With support at 20 % from year two	3.07
Implication	a family of related blocks, not unrelated ones

How this is got wrong. By planning a catalogue. At roughly one block a year, a catalogue of unrelated blocks takes a decade and each one is supported alone. The strategy that fits the arithmetic is a **family**: one architecture parameterised across a range — the same FEC core at three code rates, the same MAC at three line rates — where the second member costs perhaps a quarter of the first and shares its verification environment, its documentation structure and its support material. **Choose the first block for the family it opens, not for its own merits.**

Y8.3 What to build first

Table 497. Criteria for a first block, weighted for a house with no reputation

Criterion	Why it matters more than it looks	Good sign
A specification you can obtain	A block you cannot legally read the standard for cannot be built	Open standard, or a membership you can afford
A checkable golden model	Without an independent reference, solo verification is much weaker	Published test vectors, or an open reference implementation
Soft, not hard	A hard macro needs analogue skills and foundry access	The block is RTL from end to end
Changing standard	Incumbents' blocks go stale; a new revision resets the field	A draft is in ballot now
Few credible suppliers	You can win	Searching finds two vendors, not twenty
Adjacent to a family	Second and third members are cheap	The same core serves several rates or profiles
A customer you can name	Speculative IP is how houses die	Someone has said they would evaluate it

Graduate · **Applying these criteria is what selected this book's own subject.** The PCS and FEC sublayer of a high-speed Ethernet link scores on every row: the sublayer is soft RTL between two hard boundaries; Reed–Solomon has an independent reference in any number of open implementations and a golden model that can be verified by its algebraic properties rather than by sample values; the 802.3dj revision is in progress, which resets the incumbents; the supplier list is short; and the family extends naturally across code rates and generations. **The row that is not yet satisfied is the last one**, and this book says so rather than quietly omitting it — a named first customer is the thing that converts the other six rows from an argument into a business.

Problem. You have 39 weeks and no income. What is the order of operations that keeps you solvent?

Solution. Invert the order the technical plan suggests. **Sell services first:** contract verification, modelling or integration work pays weekly and, crucially, puts you in front of the customers who will later buy the block — the conversations are the market research. **Build the golden model and the architecture study in the gaps,** because they are the parts that need thinking rather than long uninterrupted stretches, and because they are what you show a prospective customer to prove you understand the problem. **Do the RTL and verification in a funded block** — ideally funded by a customer who wants the first instance and will accept that you retain the rights, which is a negotiation worth having explicitly and early. **Do not build speculatively for 39 weeks on savings:** the failure mode is not that the block is bad, it is that you run out of runway three weeks before the first sale, and at that point the asset is worth nothing to you and a great deal to whoever buys it from the liquidator.

Y9. Standards, Compliance and Interoperability

A protocol block is worth what it can be shown to interoperate with. That showing is a separate activity from verification, with its own vocabulary, its own costs and its own failure modes, and it is the part of the work that first-time vendors most consistently under-budget. This part lays it out.

Y9.1 Three different things called ‘testing’

Table 498. What each activity proves and what it does not

Activity	Question answered	Who runs it	What it misses
Verifica- tion	Does the block do what I specified?	You	Whether your reading of the standard is right
Conform- ance	Does the block do what the standard says?	You, or a test house, against a published test suite	Whether real partners interoperate — conformant implementations can still fail together
Interoper- ability	Does it work with this specific partner?	A plugfest, or a lab with partner equipment	Partners not present; the next revision
Certifica- tion	Will the body let me use the logo?	An accredited laboratory	Everything above — it is a process outcome, not a technical one

Two conformant implementations can fail to interoperate, and the reason is structural rather than anyone's fault. Standards contain optional features, permitted ranges and ambiguous sentences. If your block implements an option and the partner does not, both conform and neither works with the other unless the negotiation that selects it is itself implemented correctly on both sides — and negotiation code is under-tested everywhere, because testing it requires a partner that behaves differently from you. **The practical consequence is that the negotiation and fallback paths deserve more verification effort than the steady-state datapath**, which is the opposite of where effort naturally goes. In every protocol in this book, the bugs found at plugfests are concentrated in link training, capability exchange and error recovery.

Y9.2 The cost of a standard, itemised

Table 499. What conformance costs before any revenue arrives

Item	Order of magnitude	Note
The specification document	\$0–\$5,000 per document	Some are free (IETF); most industry standards are not
Body membership	\$5,000–\$50,000+ per year	Often required to obtain drafts, to attend, or to use the name
Test suite or test equipment	\$10,000–\$200,000+	Protocol analysers and compliance fixtures; rentable
Plugfest attendance	\$2,000–\$10,000 per event plus travel	The highest-value line in this table per dollar
Accredited laboratory testing	\$10,000–\$100,000 per campaign	Where a logo is required
Engineering time to fix what it finds	4–12 weeks	The line that is always omitted from the budget

Ranges, not quotations — the actual figures depend on the body and the year, and this repository has not obtained current price lists. The purpose of the table is to prevent the commonest planning error, which is budgeting zero for all six rows.

Worked example 85. Whether to certify at all

Given. A block that could be sold with or without a logo. Certification costs \$60 000 and eight weeks. Without it you expect 4 customers over three years at \$80 000; with it you expect 7, and you can charge \$95 000 because the logo removes a risk from the buyer's evaluation.

Method. Compute both revenues net of cost and time. Then note the factor the arithmetic does not contain.

Revenue without certification	320,000 USD
Revenue with certification	665,000 USD
Certification cost	60,000 USD
Eight weeks of engineering at \$120k/yr	18462 USD
Net with certification	5.8654×10 ⁵ USD
Net without	320,000 USD
Difference	2.6654×10 ⁵ USD

How this is got wrong. By treating the customer counts as data. They are forecasts, and the forecast with certification is the one you have least evidence for, since it is the counterfactual. The robust way to use this calculation is not to trust its output but to find the break-even customer count and ask whether it is plausible: here certification pays if it brings even one additional customer at the higher price. **Framed that way the decision is usually easy**, and the arithmetic has done its job by converting an argument about strategy into a question about one number.

Y9.3 Getting value from a plugfest

Table 500. Before, during and after

Phase	Do	Do not
Weeks before	Test against every partner implementation you can obtain, including open-source ones; exercise every negotiation path	Arrive to discover a problem you could have found at home
Bring	Two of everything, a logic analyser or protocol analyser, a way to re-build and reload on site, and a colleague if possible	Rely on borrowing; the other vendors are busy
Instrument	Counters, snapshot registers, and a way to capture the first failing exchange	Debug by re-running and watching
Record	Every partner, every configuration, every result — including the ones that worked	Remember it afterwards; you will not
When something fails	Determine which side deviates from the text before discussing it	Assert that the partner is wrong — roughly half the time it is you
After	Turn every failure into a regression test; publish an interoperability list	Fix the symptom and move on

Graduate ·The interoperability list is a sales document as much as an engineering one. ‘Tested against these seven implementations, at these configurations, on these dates’ answers the question a buyer cannot otherwise answer about a supplier they do not know, and it answers it with something checkable. It also has a defensive function: when a customer reports an interoperability failure with an eighth partner, the list makes it immediately clear that this is new territory rather than a regression, which changes the conversation entirely. **Keep it current and date every row**; a list without dates is read as a list of claims rather than of tests.

Problem. A partner at a plugfest insists your implementation is wrong. You believe theirs is. How do you proceed?

Solution. Stop arguing and go to the text, together. Find the clause, read it aloud, and establish what each implementation does at that point in the exchange with a capture rather than with an assertion. Three outcomes follow and all three are useful. **The text is clear and you are wrong:** fix it, and you have discovered a real bug cheaply. **The text is clear and they are wrong:** show them, courteously, and consider whether to interoperate with their behaviour anyway — if they ship in volume, your customers will meet them, and a conformant block that fails against a popular partner is a commercial problem whoever is right. **The text is ambiguous:** this is the most valuable outcome, because it means everyone has the problem. Raise it with the working group; a clarification with your name on it is reputation, and it is one of the few ways a small house becomes visible to the people who buy. **In all three cases the conduct matters more than the verdict:** plugfests are small worlds and the engineer across the table is a future customer, partner or employer.

Problem. Why should a soft-IP vendor care about compliance at all, when the customer's chip is what gets certified?

Solution. Because the customer's certification failure becomes your problem regardless of whose name is on the certificate. Practically, three things follow. **Your block must be testable in their chip:** the compliance tests require modes — loopback, pattern generation, error injection, counter read-out — that must exist in the RTL and be reachable from their software, and adding them late is expensive. **You must supply the evidence they will be asked for:** which clauses your block implements, which options, which are the customer's responsibility. And **you should have run what you can run yourself**, because a block that has never seen a compliance suite will fail one, and it is far cheaper to fail it in your lab than in theirs. **A vendor who arrives with a clause-by-clause implementation statement and their own test results is selling a lower-risk product**, and that is precisely what the premium in protocol IP is paid for.

Y10. The Register Map and the Software Interface

The register map is the part of a block that software sees, the part a customer integrates against, and the part that is hardest to change after release. It is also, in most projects, the artefact with the least design attention per hour of downstream consequence. This part works through one map in full and states the rules that each entry follows.

Y10.1 A worked map

Table 501. A minimal but complete register map, and why each register exists

Off-set	Register	Access	Reset	Why it is here
0x00	ID	RO	0x1A2B0100	Proves supply, clock, reset, bus and decode in one read (Part Y7).
0x04	SCRATCH	RW	0x00000000	Proves the write path independently of any functional side effect.
0x08	CTRL	RW	0x00000000	Everything that changes behaviour, in one register the driver can read-modify-write atomically.
0x0C	STATUS	RO	0x00000000	Live state. Never latched -- a latched status needs a clear, and a clear is a race.
0x10	IRQ_STATUS	W1C	0x00000000	Write-1-to-clear so two drivers cannot clear each other's bits.
0x14	IRQ_ENABLE	RW	0x00000000	Separate from status so masking never loses an event.
0x18	ERR_COUNT	RC	0x00000000	Read-to-clear and saturating: a counter that wraps silently is worse than one that sticks at maximum.

Seven registers. *Three of them (ID, SCRATCH, LOOPBACK) exist only for bring-up and debug, and they are the ones most often omitted by a designer who is thinking about function rather than about the week the customer spends getting first traffic.*

Table 502. ID at offset 0x00, reset 0x1A2B0100

Bits	Field	Access	Description
31:16	VENDOR	RO	Vendor identifier, constant
15:8	BLOCK	RO	Block identifier
7:0	VERSION	RO	Major.minor, BCD

Table 503. SCRATCH at offset 0x04, reset 0x00000000

Bits	Field	Access	Description
31:0	DATA	RW	Any value; no hardware effect

Table 504. CTRL at offset 0x08, reset 0x00000000

Bits	Field	Access	Description
0	ENABLE	RW	1 starts the datapath
1	SOFT_RESET	W1S	Self-clearing; resets the datapath only
2	LOOPBACK	RW	Internal loopback for bring-up
7:4	LANES	RW	Active lane count minus one

Table 505. STATUS at offset 0x0C, reset 0x00000000

Bits	Field	Access	Description
0	READY	RO	Datapath has completed initialisation
1	ALIGNED	RO	Lane alignment achieved
7:4	STATE	RO	Current link state, for debug

Y10.2 Access types, and the race each one prevents

Table 506. Register access types

Type	Behaviour	The problem it solves	Where it goes wrong
RO	Read only	—	Writing is silently ignored — specify that, or software will assume it faulted
RW	Read and write	—	Read-modify-write on a register hardware also writes loses the hardware's update
W1C	Write 1 to clear a bit	Two drivers clearing different bits do not clobber each other	A driver that writes 0xFFFFFFFF clears events it never handled
W1S / W1T	Write 1 to set / toggle	Same, for setting	—
RC	Read clears	A counter read without a separate write	A debugger that reads registers disturbs state — mark such registers so tools skip them
WO	Write only	Command registers	Unreadable state cannot be restored after suspend; prefer RW with a self-clearing bit
RW1	Writable once until reset	Lockable configuration	Software must know the lock exists

The read-modify-write race is the defect this table exists to prevent, and it is worth stating concretely. Suppose STATUS bits lived in CTRL. A driver reads CTRL, changes ENABLE, and writes it back. Between the read and the write, hardware set an error bit. The write puts back the old value of that bit and the error is lost — silently, rarely, and only under load. **The rule is structural: never mix software-written and hardware-written bits in one register**, and where an event must be cleared by software, use W1C so that the write names exactly the bits it intends. This costs one extra register and removes a class of bug that is close to undebuggable in the field.

Y10.3 One source, many outputs

A register map appears in at least six places. Maintaining them by hand guarantees they diverge, and the divergence is discovered by a driver author at the worst moment.

Table 507. What is generated from the register description, and who consumes it

Artefact	Consumer	What divergence costs
RTL register file	The design	—
C header with offsets and field masks	The driver author	A driver that writes the wrong bit
IP-XACT or SystemRDL	The customer's integration tooling	Manual integration — increasingly a purchase blocker
Documentation tables	Everyone	A datasheet that lies
UVM register model	Verification	Tests that pass against a stale model

Artefact	Consumer	What divergence costs
Debugger description	Bring-up	Wrong values read during the week they matter most

Worked example 86. The cost of maintaining six copies by hand

Given. A 60-register map, six artefacts, and a change rate of roughly 8 register changes per month during development.

Method. Count the edits and the probability that at least one is missed, assuming a 2 % chance of missing any individual edit.

Artefacts	6
Edits per month	48
Edits over a 9-month project	432
P(no edit missed) at 2 % per edit	1.62×10^{-4}
Expected number missed	8.64
Effort to build a generator	1–2 weeks
Effort saved	0.54 weeks, plus the bugs

How this is got wrong. By evaluating the generator against the edit effort alone. The edits are cheap; the missed ones are not, and the expected count here is about nine. Each is a divergence between what software believes and what hardware does, found at integration. **The generator's value is in the defects it removes, not the keystrokes,** and stating it that way is also how to justify the two weeks to a manager who sees only the keystrokes.

Problem. What should a register do when software writes a reserved bit?

Solution. Define it, and define it in the direction that leaves you room. The two defensible choices are ‘**reserved, write zero, read undefined**’ and ‘**reserved, preserve on write, read as written**’. The second is much better for forward compatibility: software does a read-modify-write and unknowingly preserves bits a future version defines, so an old driver keeps working with new hardware. The first is simpler and breaks that property. What is *not* acceptable is leaving it unspecified, because software will discover the behaviour empirically and depend on it, and you will then be unable to change it. **The same principle applies to every ‘don’t care’ in a specification:** an unspecified behaviour is not free, it is a behaviour your customers will come to rely on before you have decided what it should be.

Problem. Your block is in a power domain that can be switched off. What does that do to the register map?

Solution. It adds a requirement that is easy to miss and expensive to retrofit: **every register software may need after resume must be restorable**. That means no write-only registers whose value cannot be read back, no state that exists only in hardware counters software cannot reconstruct, and a documented save/restore list telling the driver exactly which offsets to store. It also raises a design question about which registers should be in an always-on domain — typically the ones controlling wake-up and the power sequence itself, since a register that controls power-up cannot live in the domain being powered up. **Getting this wrong produces a block that works until the first suspend/resume cycle,** which in a mobile or automotive product is within minutes of the customer first running real software on it.

Y11. The Modelling Engineer's Working Day

This book was written for someone joining a modelling team. This part describes the job concretely: what is produced, how it is judged, what the first ninety days look like, and the specific habits that distinguish a modelling engineer whose work is trusted from one whose work is checked.

A bug is a disagreement between the model and the design.

Which one is wrong is a separate question, answered by the specification.

Figure 64. The three roles and the place of the model. The dashed line is the comparison that defines a bug.

Y11.1 What a modelling engineer produces

Table 508. The deliverables, in the order they are usually needed

Deliverable	Form	Judged by
Algorithm study	Python or MATLAB, plots, a written recommendation	Whether the architecture chosen from it survives implementation
Bit-accurate reference model	C or C++, callable from the testbench	Whether it agrees with the RTL, and whether it is right when it does not
Word-length study	A sweep and a recommendation per node	Area saved against the metric held
Performance model	A cycle-approximate or cycle-accurate model	Whether the predicted throughput matches silicon
Test vectors	Stimulus and expected output	Coverage of the corners the RTL must handle
The specification's numbers	Tables in the micro-architecture document	Whether anyone has to re-derive them later

Graduate · The bit-accurate model is the deliverable the role is named for, and its value rests entirely on one property: **independence**. It must encode the *specification's* behaviour, not the design's. A model written by reading the RTL is a paraphrase, and a paraphrase agrees with the original for exactly the wrong reason. The practical discipline is to write it from the standard or the algorithm description before the RTL exists, and to resist the pressure — which is constant and comes from

everyone — to ‘just make the model match’ when the two disagree near a deadline. **Every time you make the model match, you delete a check that cannot be recovered**, and nobody will remember later which checks were deleted.

Y11.2 Fixed point is most of the work

The floating-point algorithm is usually short. Turning it into something implementable is not, and that conversion is where a modelling engineer spends most of their time. Part X1 gives the arithmetic; this is the workflow.

Table 509. The six models, and what each one answers

Stage	Model	Question	Output
1	Floating-point reference	Does the algorithm work at all?	A plot against the metric
2	Range analysis	What does each node hold?	Integer bits per node, with the basis stated
3	Quantised model with parameterised word lengths	How does the metric degrade?	A sweep, as in Part X1
4	Word-length optimisation	What is the cheapest point that passes?	A vector of word lengths and the cost model used
5	Bit-exact model	Exactly what the RTL must produce, every bit	The reference the testbench compares against
6	Corner vectors	What must the RTL handle that random stimulus will not reach?	A directed vector set

These are six models, not one model in six states. Keeping them separate means the floating-point reference remains available to answer ‘is the algorithm wrong or is the quantisation wrong?’ — a question that arises constantly and is unanswerable once the models have been merged.

Worked example 87. A disagreement, diagnosed properly

Given. The RTL and the bit-exact model differ on 3 samples in 100 000, always by one LSB, always when the input is near full scale.

Method. Do not guess. Use the model hierarchy: compare the bit-exact model against the quantised model, and the quantised against floating point, on the same three inputs. The stage where the discrepancy appears names the cause.

Differing samples	3 / 100,000
Magnitude	1 LSB
Correlated with	near-full-scale input
First hypothesis	rounding at a saturation boundary
Test	compare rounding mode at the saturating node in both
Second hypothesis	the RTL saturates before rounding, the model after
Which is right?	whichever the specification says — check

How this is got wrong. By deciding which is right from which is easier to change. The order of rounding and saturation is a real specification question with a real answer, and getting it wrong produces a block that differs from every other implementation by one LSB at full scale — which will be found by a customer comparing against a competitor. **One-LSB disagreements are the ones most often waved away and most often genuine**; the discipline is that a disagreement is closed by a citation to the specification, not by a judgement about magnitude.

Y11.3 The first ninety days

Table 510. A first quarter that builds credibility

When	What	Why this and not something more impressive
Week 1–2	Build and run the existing models and the regression	You cannot contribute to a flow you cannot run. Fix the first thing that does not build — it is a real contribution and it teaches the flow
Week 2–4	Read the specification of the block you will model, and the existing model beside it	Note every place the model differs from your reading; some are your misunderstanding and some are bugs
Week 4–6	Take a small, complete piece — one function, one corner case, one test	Complete and small beats large and partial ; the goal is a closed loop through review and merge
Week 6–10	Own a module's model end to end	Including its verification against the RTL and its documentation
Week 10–13	Find something the process misses and fix it	A missing check, an unreproducible result, a manual step. This is what distinguishes you

*The pattern is deliberate: **run before reading, read before writing, small before large, and process improvement last** — because a process criticism from someone who has not yet shipped anything through the process is ignored, and the same criticism after ten weeks is acted on.*

The failure mode of a new modelling engineer is silent disagreement. You read the specification, you believe the existing model is wrong, and you say nothing because you assume the experienced people have a reason. Sometimes they do, and hearing it is how you learn. Sometimes they do not, and the bug ships. **The correct move is neither silence nor an accusation: it is a question with the clause number attached.** ‘Clause 7.3.2 says the rounding happens before saturation and I read the model as doing the reverse — what am I missing?’ costs nothing if you are wrong and is extremely valuable if you are right. Engineers who ask this way get answers; engineers who assert get arguments.

Problem. You are asked to model a block whose specification is an internal document written by an architect who has left. What do you do?

Solution. Treat the gap as the first deliverable. **Write down what the document does not determine** — every place where two readings are possible, every constant with no stated basis, every behaviour on an illegal input — and circulate that list. It is immediately useful to everyone and it is the cheapest thing you can produce in week one. **Then resolve the list by evidence in this order:** existing RTL or a previous generation, since what shipped is a fact; test vectors or captured data, which settle behaviour without settling intent; the people who integrated against it, who know what they relied on; and finally a decision recorded as a decision, with your name and the date, for the items nothing resolves. **What you must not do is make the choices silently inside the model.** A model containing twenty undocumented decisions is not a reference; it is a second design, and when it disagrees with the RTL nobody will be able to say which is right.

Problem. Your model and the RTL agree perfectly on the first day of integration. Is that good news?

Solution. It is news that needs checking before it is good. Perfect agreement on day one has three explanations and only one of them is happy. **The comparison may not be running** — a checker that is disabled, a stimulus that never reaches the block, a comparison of two constants; this is the first thing to rule out, and the way to rule it out is to **break something deliberately and confirm the comparison notices**, which is the same self-check the agent in Part Y4 performs every round. **The model may have been written from the RTL**, in which case agreement is tautological. **Or the block may genuinely be simple and correct**, which does happen. Establishing which costs half an hour and is the single highest-value half hour in an integration, because everything downstream rests on the answer.

Y12. High-Level Synthesis in a Small Design House

High-level synthesis promises to turn C++ into RTL, which for a one-person house sounds like a way to multiply headcount. It is a real tool with a real place, and the place is narrower than the marketing and wider than the scepticism. This part states where it wins, where it does not, and what this repository measured when it tried to synthesise a production C++ library with an open-source tool.

Y12.1 What HLS actually decides for you

The three transformations, and which one is the hard one

	Step	Justification
1	Scheduling: assign each operation to a clock cycle, respecting data dependences and the target period.	<i>The tool solves a constrained scheduling problem, typically with a list-scheduling heuristic or an ILP formulation for small regions.</i>
2	Allocation: decide how many of each resource exist.	<i>Two multiplies in different cycles may share one multiplier.</i>
3	Binding: assign operations to specific resource instances, and variables to registers or memories.	<i>Introduces multiplexers, which is where a naive binding loses the timing the scheduler thought it had.</i>
4	All three are driven by pragmas , not by the C++ semantics.	<i>This is the fact that determines everything else.</i> <i>The same C++ with different pragmas produces designs differing by orders of magnitude in area and throughput, which means the C++ is not the design — the C++ plus the pragmas plus the tool version is the design.</i>
5	So HLS source is not portable between tools in any practical sense.	<i>The pragma dialects differ, the library types (<code>ap_fixed</code>, <code>hls::stream</code>) differ, and the scheduling behaviour differs. Measured in this repository: a production Xilinx Vitis library did not build under an open-source HLS tool without modification.</i>

Table 511. Where HLS wins and where it does not

Situation	HLS	Why
Datapath-heavy, regular loops (filters, transforms, linear algebra)	Strong	Scheduling a loop nest is exactly what the tool is good at
Design-space exploration — ten variants of one algorithm	Very strong	Changing a pragma is minutes; rewriting RTL is days. This is the best argument for HLS
Algorithm still changing	Strong	The C++ stays readable as the algorithm moves
Control-dominated protocol logic	Weak	A state machine expressed as C++ control flow is harder to read and to verify than the FSM it becomes
Cycle-exact interface timing	Weak	The tool owns the schedule; you are negotiating with it
Area- or timing-critical blocks at the frequency limit	Weak	The last 20 % needs control the abstraction removes
Code you must hand to a customer as portable RTL	Fine	Ship the generated RTL; the customer never needs the C++

Graduate · **The strongest case for HLS in a small house is exploration, not production.** The question ‘what does this algorithm cost at four different parallelism factors?’ takes an afternoon in HLS and a fortnight in RTL, and the answer changes the architecture. Having taken the decision, writing the production block in RTL is often still the right call — and the HLS model remains useful as a golden reference, since it is C++ that is known to produce the same numbers. **Used this way, HLS is a modelling tool that happens to emit RTL**, which fits the role this book is written for.

Y12.2 What this repository measured

This repository built an open-source HLS tool from source and attempted to synthesise a production vendor C++ library with it. The findings are recorded in `survey/synth/합성결과.md` (144 lines) and are summarised here because they are the kind of result that is rarely written down.

Table 512. Three independent blockers, isolated by single-variable experiments

Blocker	Evidence	What it means for a user
Pragma dialect	Vendor pragmas are not recognised by the other tool; the code compiles and schedules differently	HLS source does not port. Budget a rewrite, not a recompile
Library types	A crash in the tool's own pass while handling a streaming class passed by value	The vendor's stream and fixed-point classes are part of the vendor's tool, not part of C++
Template instantiation cost	Heavily templated fixed-point code expands enormously before synthesis begins	Compile time can exceed the time budget before any hardware is generated

Two lessons from that exercise are worth more than the result itself. First, **the blockers were only separable by controlled experiments:** all three appeared as ‘it does not work’ until each was isolated with one variable changed at a time, and before that isolation it would have been easy — and wrong — to report a single cause. Second, an early attempt to name the cause was withdrawn because the run had timed out before reaching the pass in question, so the claim was a guess and not a measurement. **The rule that produced both corrections is the one this whole book applies: a number or a cause you have not measured is not a finding, however confident you are.**

Y12.3 Verifying HLS output

Table 513. The three levels of HLS verification

Level	What it compares	Catches	Cost
C simulation	The C++ against your test vectors	Algorithm bugs	Seconds — run constantly
C/RTL co-simulation	The generated RTL against the same C++ on the same vectors	Tool bugs and pragma misunderstandings	Minutes to hours
RTL verification	The generated RTL in its real environment	Interface and integration problems the co-simulation harness hides	As for any RTL

Undergraduate review · **Why C/RTL co-simulation is not optional.** It is tempting to reason that if the C++ is correct and the tool is correct then the RTL is correct. The second premise is the problem: HLS tools have bugs, and more commonly the *pragmas do not mean what the writer thought* — a dependence the tool was told to ignore was real, a loop it was told to pipeline could not be, an interface protocol was inferred differently from what the integrator expects. Co-simulation catches all of these for the cost of running the vectors twice. **It is also the only thing that makes the C++ usable as a golden model afterwards**, since it establishes that the two really do agree.

Worked example 88. When HLS pays for itself, as arithmetic

Given. An exploration of one algorithm at four parallelism factors and three word lengths — twelve design points. RTL: 3 days per point. HLS: 2 days to set up plus 2 hours per point. Both need the results to be trustworthy.

Method. Count the days for each route, including the HLS learning and verification overhead that is easy to omit.

Design points	12
RTL route, days	36
HLS setup, days	2
HLS per point, days	0.25
HLS route, days	5
Plus co-simulation of the chosen point, days	2
HLS total	7
Saving	29 days

How this is got wrong. By counting the saving and then shipping the HLS output without the verification days. The arithmetic above holds only because the last two rows are included; an HLS flow without co-simulation is faster and produces RTL nobody should trust. The second common error is to count the setup as a one-off when it is per-project: tool versions, library versions and pragma behaviour change, and a flow that worked last year needs re-establishing. **Budget the setup every time and the saving is still large for exploration and small or negative for a single production block** — which is exactly the recommendation in Y12.1, now with numbers behind it.

Problem. A customer asks whether your block was written in RTL or generated from HLS. Does it matter, and how do you answer?

Solution. It matters to them for three legitimate reasons and you should answer plainly. **Maintainability:** if they must modify the block, generated RTL is unpleasant to edit, so they need either the C++ and the flow, or a commitment that you will make changes. **Quality of results:** generated RTL is usually larger and slower than good hand RTL at the same function, and if they are area- or frequency-constrained that is their business. **Predictability:** regenerating with a different tool version can change the result, so they will want to know the RTL they receive is frozen and verified as delivered, not regenerated on demand. **The answer that satisfies all three is to ship frozen, verified RTL with its synthesis and timing reports, and to state the provenance.** Concealing it is the bad option: it is discoverable from the generated code's shape in about five minutes, and being caught concealing something harmless costs more than the thing concealed.

Y13. Getting Hired into a Modelling Team

This part is about the interview and the portfolio, treated as an engineering problem: what does the hiring side actually need to learn about you, and what evidence answers it fastest? The answer is unusually concrete for this kind of advice, because modelling work produces artefacts that can be shown.

Y13.1 What the interviewer is trying to find out

Table 514. The four questions behind a modelling interview

The question	How it is usually asked	What actually answers it
Can you write a correct model?	A coding exercise, often a fixed-point or protocol task	Code that handles the corners and says which it handles
Do you know why the model exists?	'How would you verify this block?'	An answer that mentions independence and what a disagreement means
Do you understand the hardware?	'Why is this architecture like this?'	Reasoning from timing, area or bandwidth — numbers, not adjectives
Will you say when something is wrong?	'Tell me about a time...', or a deliberately flawed premise in a question	Noticing the flaw and saying so, politely, is the whole test

Graduate · The fourth question is weighted more heavily than candidates expect, and it is the one this book's discipline speaks to directly. A modelling engineer's value is that they are an independent check. An engineer who defers to the design team's reading of the specification is not performing the function they were hired for, however good their code is. Interviewers probe this deliberately — a question with a wrong assumption embedded, a requirement that contradicts an earlier one — and the answer they want is neither silence nor combativeness but the thing this book keeps recommending: **name the discrepancy, cite the source, and ask.**

Y13.2 A portfolio that is evidence rather than assertion

Table 515. Portfolio items, ordered by what they prove per hour of effort

Item	Concretely	What it proves
A bit-accurate model of a standard block	RS or BCH decoder, a CIC decimator, a 64b/66b PCS	Shows you can read a specification and produce something checkable
Its test suite, with mutation results	'These 14 injected faults; the suite catches 13; here is the escape and why'	Almost nobody does this, and it is the single most convincing artefact
A word-length study	A sweep, a cost model, a chosen point with a reason	Shows you understand the actual daily work
An RTL block compared against the model	Even a small one, with the comparison automated	Shows you have closed the loop end to end
A written page on a bug you found	Symptom, hypotheses, the measurement that discriminated, the fix	Demonstrates method, which is what is being hired
A contribution to an open project	A fix, a test, a documentation improvement in a real codebase	Independent evidence that someone reviewed and merged your work

Depth beats breadth here. One block modelled properly, with its verification and its written reasoning, is worth more than six half-finished repositories — because the thing being assessed is whether you finish and whether you check, and only a finished, checked thing can show that.

Worked example 89. Where the hours go, and what each hour buys

Given. 120 available hours over three months, to be spent on a portfolio.

Method. Allocate against the four interview questions, weighting by how much evidence each hour produces.

Model of one standard block	40 h
Test suite with mutation measurement	30 h
Small RTL implementation and comparison	25 h
Written documentation and a bug write-up	15 h
Polish, README, reproducibility	10 h
Total	120 h
Questions from Y13.1 this evidences	all four

How this is got wrong. By spending all 120 hours on the model. A beautiful model with no test suite answers one of the four questions; the same model with 30 hours moved into verification answers three. The most common portfolio failure is an imbalance in exactly this direction, because modelling is the enjoyable part. **The hours spent proving the model is right are the hours that differentiate**, precisely because they are the ones most candidates skip.

Y13.3 Interview questions you should expect, and how to think about them

Table 516. Common questions and the shape of a good answer

Question	What they want to hear
'How do you know your model is right?'	Independence of source; a third-party reference where one exists; property-based checks rather than sample values; fault injection to prove the checks bite
'The RTL and your model disagree. What now?'	Reproduce minimally, then go to the specification. Do not edit the model to match , and say so
'How many bits does this filter need?'	'Against what metric?' — then range, then sweep, then the knee. Asking for the metric first is most of the answer
'Why not just use floating point?'	Area, power and determinism; then the accumulation and associativity arguments from Part X9
'Our coverage is 100 %. Are we done?'	Code coverage measures execution, not checking. Offer mutation score and checker coverage as the evidence that would settle it
'Tell me about a hard bug.'	The method, not the heroics: hypotheses, the measurement that discriminated, what you changed in the process afterwards

One answer to avoid: 'I would add more tests.' It is the reflex response to every verification question and it is almost never the best one, because it does not say *which* tests or how you would know they were enough. The answers that distinguish a candidate name a measurement: mutation score, checker coverage, a comparison against an independent reference, a property that holds for all inputs rather than a vector that holds for one. **Every one of those is something this book has computed somewhere**, and being able to say 'I would measure X and here is what X would tell us' is the difference between sounding careful and being useful.

Problem. You are asked to estimate something you do not know — how many gates a block needs, how long a task takes. What do you do?

Solution. Estimate out loud, from decomposition, and say what would sharpen it. The interviewer is not testing recall of a number; they are watching whether you can bound an unknown, which is most of engineering judgement. A good answer names the decomposition ('the multiplier array is about n^2 full adders, a full adder is about six gates, so...'), states the assumption that matters most, gives a range rather than a point, and ends with the measurement that would collapse the range. **Refusing to estimate is the worst answer** and a confident unqualified number is the second worst; the habit being looked for is the one Part X1 applies to word lengths and Part Y8 to schedules — a bound, its basis, and what would improve it.

Problem. You have no industry experience and no degree from a famous university. What actually compensates?

Solution. Artefacts, and one specific kind of them. A repository containing a model, its test suite, a mutation measurement of that suite, and a written page explaining a bug it caught is evidence that nobody can produce without having done the work — and it is checkable in ten minutes by the person deciding whether to interview you. Two things amplify it. **Contributions to a real open project carry an independent review signal:** someone with no reason to flatter you merged your change. And **a written explanation of something difficult** — a blog post deriving a result, a clear note on a standard's ambiguity — demonstrates the communication half of the job, which is half of it. What does not compensate is a list of technologies; every candidate has one, and it distinguishes nobody. **Build one thing completely and write down how you know it works.**

Y14. The Flow a One-Person House Can Actually Run

Commercial EDA licences cost more per year than a one-person house earns. That fact shapes what such a house can sell, and the honest answer is that a great deal is possible with free tools and one thing is not. This part sets out which is which, and measures what is actually installed in the environment this book was built in.

Y14.1 What is installed here, measured

Table 517. Tools present in the container this book was rendered in, checked at build time

Tool	Role	Present	Version reported
iverilog	Event-driven Verilog/SystemVerilog simulation	yes	Icarus Verilog version 12.0 (stable) ()
verilator	Cycle-accurate compiled simulation; fast regressions	yes	Verilator 5.020 2024-01-01 rev (Debian 5.020-1)
yosys	RTL synthesis to a gate netlist	yes	Yosys 0.33 (git sha1 2584903a060)
gtkwave	Waveform viewing	not installed	—
python3	Modelling, scripting, this book	yes	Python 3.11.15
gcc	Reference models in C/C++	yes	gcc (Ubuntu 13.3.0-6ubuntu2~24.04.1) 13.3.0

Probed by running each tool. *The verification agent of Part Y4 uses the first of these and nothing else, which is the point: a complete model-versus-RTL regression loop needs one free simulator.*

Y14.2 What the free flow can and cannot do

Table 518. Capability, honestly assessed

Activity	Free flow	Note
Modelling and algorithm work	Complete	Python, NumPy, C++ — nothing is missing
RTL simulation	Complete for most purposes	Verilator is fast; Icarus handles constructs Verilator does not
UVM	Partial	UVM needs constrained randomisation and full class support; free simulators have improved but are not equivalent. cocotb is a viable different answer
Formal property checking	Usable	SymbiYosys and its solvers; capacity below commercial tools
Lint and CDC	Partial	Verilator lint is good; dedicated CDC sign-off tools have no free equivalent
Synthesis to a gate netlist	Yes	Yosys, with open cell libraries
Place and route	Yes for open PDKs	OpenROAD and the open PDK flows
Sign-off STA in a commercial process	No	Needs the foundry's timing libraries, which come with an NDA and a commercial tool
Tape-out to a commercial foundry	No	This is the line a free flow does not cross

Graduate · **The line falls exactly where a soft-IP business wants it.** Everything on the seller's side of a soft-IP transaction — modelling, RTL, verification, and enough synthesis to quote area and frequency credibly — is reachable with free tools. Everything on the buyer's side — sign-off in their process, with their libraries, in their flow — is theirs to run and they already have the licences. **A design house selling RTL therefore does not need a tape-out flow**, and recognising that is the difference between a viable plan and one that requires six figures of tooling before the first sale. The caveat to state to customers is equally clear: your frequency and area numbers come from an open flow and an open library, and they will re-run them; give them the scripts so they can.

Worked example 90. What credible area and frequency numbers cost to produce

Given. You want to quote '150 kGE at 500 MHz' for a block, with evidence, using only free tools.

Method. Enumerate what is needed and what each step actually establishes.

Synthesis with Yosys to an open library	area in gate equivalents
Static timing with OpenSTA on that netlist	a frequency, in that library
What this does <i>not</i> establish	performance in the customer's process
What makes it credible anyway	the <i>ratio</i> transfers; publish the library and the scripts
Additional cost	0 USD
What a customer will still do	re-run it in their flow
What they are really buying	the assurance that the number is not invented

How this is got wrong. By quoting a number from an open flow as though it were a sign-off number. It is not, and a customer who discovers the elision stops trusting the rest of the datasheet. The correct presentation names the library, the tool and the version, states that it is a pre-layout estimate in an open process, and offers the scripts. **That presentation is more persuasive than an unattributed larger claim**, for the same reason the known-issue list of Part Y5 is: it is checkable.

Y14.3 A regression setup that survives one person

Table 519. What to automate first, in order of return

Automate	Why it is first	Effort
One command that runs everything	If the regression is three commands, it will be run less often, and the one that is skipped is the one that would have caught it	Hours
Deterministic seeds recorded with results	A failure you cannot reproduce is a failure you cannot fix	Hours
A self-check that the checkers bite	Otherwise a green regression means nothing — the theme of this entire book	A day
Results to a ledger, not to a terminal	You will be asked what changed between last week and now	A day
Overnight running with the correct detachment	Part Y4's setsid/nohup/disown pattern — the obvious way silently does nothing	Hours
Mutation testing of the suite	Turns 'we have tests' into a number you can quote	Days — and it is what a customer remembers

The failure that ends solo projects is not a hard bug; it is losing the ability to reproduce. Six months in, with several branches, a half-changed model and results in a terminal scrollbar, the question 'did this ever pass?' becomes unanswerable, and from that point every decision is a guess. The defence is cheap and must be built before it is needed: **every run records**

its commit, its seeds, its tool versions and its results to a file that is committed. This book's own repository does exactly this, and the rule that produced it is worth repeating: a check that leaves no record is a check nobody can audit, including you.

Problem. Which free simulator should a one-person house standardise on?

Solution. Both, for different jobs, and the reasoning generalises. **Verilator** for the bulk regression: it compiles to C++ and runs one to two orders of magnitude faster than event-driven simulation, which is what makes an overnight run worth having; its restrictions (two-state by default, synthesisable subset, no timing constructs) are mostly acceptable for a testbench driven from C++ or cocotb. **Icarus** for the cases Verilator refuses: four-state X-propagation, gate-level simulation with delays, and legacy constructs. **The important discipline is to keep the RTL compiling under both**, because each catches things the other permits — Verilator's lint is stricter than most commercial tools, and Icarus's four-state semantics catch reset and initialisation bugs that a two-state run hides. Two simulators disagreeing about your design is information, and it is free.

Y15. A Complete Worked Project: RS-KP4

This part takes one block from a specification through to a delivery package, with the numbers computed rather than estimated. It uses the code that is already in this repository — the field arithmetic and the decoder of Part X5 — and it states, at each step, what exists and what does not, so the reader can see the difference between a worked example and a finished product.

Figure 65. The decoder architecture. The delay FIFO is the block’s dominant memory and the reason latency is quoted in code-words.

Y15.1 The parameters, and which are still unconfirmed

Table 520. The parameter set, with the confidence of each entry

Parameter	Value used	Confidence	Where it is fixed
Field	$GF(2^{10})$	confirmed by the code length	—
Primitive polynomial	0x409 assumed	NOT confirmed	Fixed by IEEE 802.3 Clause 91, which this repository has not read
First consecutive root fcr	0 assumed	NOT confirmed	Same clause
Symbol bit order	MSB first assumed	NOT confirmed	Same clause
n, k	544, 514	confirmed — the code’s name	—
t	15	derived: $(n-k)/2$	—

Three of six are assumptions. The model in this repository takes all three as arguments with the assumption marked, and its tests check properties that hold whatever the values are — that up to t errors are always corrected and that beyond t the decoder does not silently return the input. When the clause is obtained, only the defaults change.

This is what it looks like to build honestly on an unread specification. The alternative — pick a polynomial, hard-code it, and proceed — produces a block that works perfectly against itself and fails at the first interoperability test, with the cause buried in a constant nobody questions. Parameterising costs nothing and the marked confidence costs one column in a table. **What it buys is that the unread clause remains visible** instead of dissolving into an assumption, which is precisely the failure Part Y6 is written to prevent.

Y15.2 Sizing the block from the standard's rate

Table 521. Parallelism required at 53.125 GBd, one symbol per 10 bits

De-serialisation	Digital clock (MHz)	Symbols per clock	Symbols processed in parallel	Datapath width (bits)	Clocks per code-word
4	830	64.01	65	650	8.369
8	415	128	129	1,290	4.217
16	208	255.4	256	2,560	2.125
32	104	510.8	511	5,110	1.065

The third column is the block's fundamental parallelism: at 830 MHz the decoder must absorb 64 symbols every cycle. **Every stage of the architecture must be replicated or restructured to that width, and that replication, not the algorithm, is where the area goes.**

Worked example 91. Where the area actually goes

Given. RS(544,514), $t = 15$, 64 symbols per cycle at 830 MHz.

Method. Count the three structures separately: the syndrome computation (parallel, wide), the key equation (serial, narrow) and the Chien search (parallel, wide). The asymmetry is the architectural fact.

Syndromes to compute	30
GF multipliers for syndromes, unparallelised	30
At 64 symbols per cycle	1,920
Berlekamp–Massey multipliers (serial, $\sim 2t$)	30
BM cycles per codeword	30
Chien: evaluate σ at 64 positions per cycle	960
Ratio of wide structures to the key equation	96×
Delay FIFO	5,440 bits per codeword in flight

How this is got wrong. By optimising Berlekamp–Massey. It is the algorithmically interesting stage, it is what the literature discusses, and here it is about one per cent of the multipliers. **The syndrome and Chien stages dominate because they are replicated 64 ways** and BM is not. The architectural leverage is therefore in sharing and folding those wide stages — the standard techniques being common-subexpression sharing across the syndrome constants and a folded Chien search — and in nothing else. **Compute the replication factor before deciding what to optimise**, in any block.

Y15.3 What exists in this repository and what does not

Table 522. State of the project, stated plainly

Item	State	Where
Field arithmetic with verified axioms	Exists	gf.py, 10 tests
Encoder and bounded-distance decoder	Exists	rs.py, 13 tests including mutation guards
Measurement that refuses a zero-error pass	Exists	rs. 측정()
Prior-art survey with confidence markers	Exists	paper/선행조사/PCS_FEC계층_IP.md
A syndrome-step RTL block verified against the model	Exists	edu/agent/blocks/rs_syndrome/
Full parallel decoder RTL	Does not exist	—
Berlekamp–Massey RTL	Does not exist	—

Item	State	Where
The three unconfirmed constants	Still unconfirmed	Needs the IEEE document
Concatenated inner code (802.3dj)	Not started	—
A named first customer	None	—

Graduate · Listing what does not exist is the point of this section. A worked example that presents a partial project as a finished one teaches the wrong lesson twice: it misleads about the effort, and it models the behaviour — quiet omission of the incomplete parts — that this book spends two chapters warning against. The honest summary is that this repository contains a *verified reference model and one verified RTL primitive* for a block whose full implementation is most of Part Y8's 39-week plan, and that three of its parameters await a document that must be purchased.

Problem. Given that state, what are the next three actions, in order?

Solution. First, obtain the clause. Three unconfirmed constants block every downstream claim of interoperability, and no amount of RTL removes that block; until they are confirmed the project can produce a correct decoder for a code that may not be the standard's. This is a purchase and a fortnight of reading, and it is the highest-value action available. **Second, build the syndrome stage at full parallelism and verify it against the model,** because the sizing example above says that stage dominates the area, so the area and frequency claims — the numbers a customer asks for first — are determined by it. One wide stage, synthesised and timed, converts an estimate into a measurement. **Third, find a customer conversation before writing the key equation,** because everything after the syndrome stage is a large effort whose requirements (latency budget, code rate set, concatenation) the customer determines, and guessing them is how the 39 weeks turn into 60. **Note that the technically interesting work is third on this list,** which is usually where it belongs.

Volume II — Production Source Code

This volume reproduces **156,976 lines** of source from 44 blocks that are shipping in silicon or sold as commercial IP. Nothing is paraphrased: every line is read from disk and printed with its real line number, so a citation of the form `file:line` anywhere in this book can be followed directly.

Each block is preceded by four notes — **What** it is, **Why** it exists (what fails without it), the **EECS concepts** it rests on, and a **practice note** for engineers who must work with it. An **API dictionary** then lists every module, class, function, parameter, port, macro and typedef that the block declares, with the arguments each one takes, because names alone are ambiguous.

The API dictionary is generated by pattern extraction, not by a full language front end. It is therefore complete enough to navigate by and may miss unusual declarations; the verbatim source that follows each table is authoritative.

MIPI CSI-2 수신기 -- 패킷 디코더 · 레인 정렬 · RAW 언팩

What this is. A working MIPI CSI-2 receiver in Verilog: byte and lane aligners, the packet decoder, RAW8/10/12 depackers, an output reformatter, and a debayer filter.

Why it exists. Because it is the concrete form of every block named in Chapter P1. Reading `mipi_rx_lane_aligner.v` alongside the description of lane deskew, and `mipi_rx_raw12_depacker.v` alongside the explanation of RAW packing, turns an abstract block diagram into something that can be modified.

Undergraduate review · EECS concepts. Packet framing and synchronisation; ECC and CRC; bit-packing and unpacking; multi-lane deskew; line buffering for neighbourhood operations.

Graduate · Practice note. Start with `mipi_rx_raw_depacker.v`. The bit-slicing there is exactly the part that Chapter P1 identifies as where verification effort concentrates, and seeing how few lines it takes — and how many ways it can be wrong — makes the point better than any description.

14 Takes 4x10bit pixel from RAW10 depacker module @mipi byte
15 clock output 4x24bit RGB for each pixel , output is delayed by 2
16 lines
17 Implement Basic Debayer filter, As debayer need pixel infrom
18 neighboring pixel which may be on next or previous display line,
19 so input data is written onto RAM, only 4 lines are stored in
20 RAM at one time and only three of the readable at any give time ,
21 RAM to which data is written to can not be read.
22 as we have enough info in RAM, 4 10bit pixel will be converted
23 to 4x24bit RGB output
24 First line is expected to RGRG , second line GBGB
25 */

MIPI CSI-2 수신기 (1세대)

What this is. An earlier generation of the same receiver, targeting a different FPGA family.

Why it exists. Because comparing two implementations of one specification is instructive. The differences show which parts are forced by the standard and which are choices — the distinction a specification writer must be able to make.

Undergraduate review · EECS concepts. Design portability; the boundary between specification and implementation.

Graduate · Practice note. A useful exercise: list the differences between the two versions and classify each as required by the standard, forced by the target device, or a free choice. That classification is the substance of a good specification document.

14 Takes 4x10bit pixel from RAW10 depacker module @mipi byte
15 clock output 4x30bit RGB for each pixel , output is delayed by 2
16 lines
17 Implement Basic Debayer filter, As debayer need pixel infrom
18 neighboring pixel which may be on next or previous display line,
19 so input data is written onto RAM, only 4 lines are stored in
20 RAM at one time and only three of the readable at any give time ,
21 RAM to which data is written to can not be read.
22 as we have enough info in RAM, 4 10bit pixel will be converted
23 to 4x24bit RGB output
24 First line is expected to RGRG , second line GBGB
25 */

이더넷 MAC · 10G BASE-R PCS · XGMII/GMII

What this is. A widely used open Ethernet implementation: 1G and 10G MACs, the 10G BASE-R PCS (64b/66b encode and decode, block synchronisation, BER monitor), and the GMII/XGMII interface adapters.

Why it exists. Because it is the reference point for Chapter P3. It shows what a complete MAC contains, and — equally usefully — what it does not: there is no RS-FEC and no 100G multi-lane PCS here, which is precisely the gap a new IP could fill.

Undergraduate review · EECS concepts. Framing; CRC-32; inter-frame gap; 64b/66b line coding; scrambling for DC balance; block synchronisation state machines.

Graduate · Practice note. Read `xgmii_baser_enc_64.v` and `xgmii_baser_dec_64.v` together with Chapter K2's account of 64b/66b. The two-bit sync header and the block type field are visible directly in the code, and the scrambler is in `lfsr.v` — the same LFSR structure that Chapter Z3 introduces as CRC, PRBS and scrambler at once.

PCIe 코어 (추가)

What this is. Additional PCIe interface logic: transaction handling and DMA.

Why it exists. Because Chapter P2 describes the layering abstractly and this shows the transaction layer as code. DMA and descriptor handling, in particular, are where the throughput analysis of that chapter becomes concrete.

Undergraduate review · EECS concepts. Layered protocols; credit-based flow control; descriptor rings; DMA engines.

Graduate · Practice note. Trace how outstanding requests are tracked. Chapter P2 argues that tag capacity rather than link width limits read throughput; the tag management logic here is where that limit physically lives.

AES 골든 모델 (C)

What this is. A 573-line C implementation of FIPS-197 AES: the S-box table, `xtime`, the four round functions, key expansion, and ECB/CBC/CTR modes.

Why it exists. To define what is correct. Judging an RTL implementation requires an expected value computed independently. This file produces it. The complete absence of hardware concepts — no clock, no ports, no state machine — is deliberate: only the *meaning* remains.

Undergraduate review · EECS concepts. Finite-field $GF(2^8)$ arithmetic; substitution-permutation network structure; Shannon's confusion and diffusion.

Graduate · Practice note. Note that `xtime` multiplies by a mask rather than branching. This keeps execution time independent of the data — the most basic timing-side-channel discipline — and it is worth preserving even in a model.

```

1 /*
2
3 This is an implementation of the AES algorithm, specifically
4 ECB, CTR and CBC mode.
5 Block size can be chosen in aes.h - available choices are
6 AES128, AES192, AES256.
7
8 The implementation is verified against the test vectors in:
9 National Institute of Standards and Technology Special Pub-
10 lication 800-38A 2001 ED
11

29
30 NOTE: String length must be evenly divisible by 16byte
31 (str_len % 16 == 0)
32 You should pad the end of the string with zeros if
33 this is not the case.
```

```

30 For AES192/256 the key size is proportionally larger.

AES·SHA·MD5 C 참조 구현

What this is. Brad Conte's reference implementations of common cryptographic primitives, each self-contained in one file.

Why it exists. To serve as a second, independent implementation. A single golden model cannot reveal its own misreading of a standard. Two implementations written by different authors from the same document agree only where both read it the same way.

Undergraduate review · EECS concepts. Merkle–Damgård construction; compression functions; padding rules; collision resistance.

Graduate · Practice note. Cross-validating two independent models early makes the later triage of an RTL mismatch much cheaper, because the possibility “the model is wrong” can be dismissed in minutes rather than days.

6 * Details:   Performs known-answer tests on the corresponding AES
7             implementation. These tests do not encompass the
8             full range of available test vectors and are not sufficient
9             for FIPS-140 certification. However, if the
10            tests pass it is very, very likely that the code is correct
11            and was compiled properly. This code also serves as
12            example usage of the functions.

1 /
2 * Filename:    blowfish_test.c
3 * Author:      Brad Conte (brad AT bradconte.com)
4 * Copyright:
5 * Disclaimer:   This code is presented "as is" without any guar-
antees.
6 * Details:     Performs known-answer tests on the corresponding
Blowfish
7                implementation. These tests do not encompass
the full
8                range of available test vectors, however, if
the tests
9                pass it is very, very likely that the code is
correct
10               and was compiled properly. This code also
serves as
11               example usage of the functions.

*****
2 * Filename:   sha256.c
3 * Author:    Brad Conte (brad AT bradconte.com)
4 * Copyright:
5 * Disclaimer: This code is presented "as is" without any guar-
antees.
6 * Details:   Implementation of the SHA-256 hashing algorithm.
SHA2
7             SHA-256 is one of the three algorithms in the
8             specification. The others, SHA-384 and SHA-512,
are not
9             offered in this implementation.
10            Algorithm specification can be found here:
11            * http://csrc.nist.gov/publications/fips/
fips180-2/fips180-2withchangenotice.pdf
12            This implementation uses little endian byte or-
der.

AES 코어 (Verilog)

What this is. Joachim Strömbergson's AES in Verilog: encipher and decipher cores, S-box, key memory.

Why it exists. To provide the plain-RTL baseline. Neither HLS C++ nor hardened security RTL, it shows how small AES is when only the function is implemented. Comparing it with OpenTitan's 17,000 lines isolates exactly what side-channel and fault countermeasures cost.

Undergraduate review · EECS concepts. Register-transfer abstraction; finite state machines; separation of datapath and control.

Graduate · Practice note. When evaluating any IP, the useful question is not “how many lines?” but “what threat model does it assume?” Two blocks implementing the same standard under different threat models are different products.

SHA-256 코어 (Verilog)

What this is. SHA-256 with the compression function and the message schedule (W memory) as separate modules.

Why it exists. To show that a hash's message schedule is a block in its own right. Each of the 64 rounds consumes one W word, and the W words are generated recursively from earlier ones. Whether to expand all 64 in advance or to maintain a 16-word rotating buffer is a direct area–latency trade.

Undergraduate review · EECS concepts. Mapping a recurrence to hardware; circular buffers; area–time trade-offs.

Graduate · Practice note. Read sha256_w_mem.v first. The 16-word rotating buffer idiom recurs in LDPC message storage, FFT delay lines and FIR delay chains; recognising it once makes all of them familiar.

OpenTitan AES -- 양산 보안 RTL

What this is. The AES block from a production security chip: cipher core, triplicated control FSMs, six S-box implementations, masking and clearing PRNGs, CTR and GCM support, shadowed registers, TL-UL interface.

Why it exists. It contains the entire difference between an AES that is functionally correct and one that can be shipped. The algorithm is identical to the plain Verilog core. Everything else defends against power analysis, fault injection, misconfiguration and data remanence.

Undergraduate review · EECS concepts. Differential power analysis; threshold implementations and probing security; fault-tolerant design through complementary redundancy; CMOS switching energy $P \propto \alpha CV^2 f$.

Graduate · Practice note. Open `aes_sbox_dom.sv` (1,077 lines) beside `aes_sbox_lut.sv` (120 lines). They compute the same mathematical function at nine times the size. **A functional regression cannot distinguish them** — which is precisely the boundary a modelling engineer must understand and state.
